The calculation of the first return in 1759 was not left to the rough prediction of Halley. In the rising school of French mathematicians who were destined to exploit the work of Newton, Clairaut (1713–1765) was the first to distinguish himself by researches on the figure of the earth, planetary perturbations and the lunar theory. On the instigation of Lalande he undertook to calculate the perturbations of the Comet, making it a condition that he should have the help of Mme. Lepaute (née de la Brière) as computer. Clairaut devised the methods to be used in the then novel task, and with this aid finished the necessary calculations in eighteen months, so that he could announce the result before the end of 1758. The predicted time of perihelion was April 13 in the following year, thus overshooting the mark by a whole month, for the actual date was March 12. There was nothing surprising in the discrepancy, because the masses of the planets were very imperfectly known. An error in the assumed mass of Saturn was chiefly responsible, and neither Uranus nor Neptune was so much as known to exist. The outcome of the pioneer research of this kind must be considered entirely successful.

Once more the Comet has started on its long journey. Before it returns, mathematical astronomy will have made great strides. Euler will not see it again: he is too nearly the contemporary of Clairaut. Neither will Lagrange, nor Laplace. But all these and others will have enriched science by their immortal labours, and there are many to hand on the torch. No fewer than four astronomers undertook the task of calculating the perturbations on this occasion, of whom one carried them back as far as 1607. For the date of perihelion in 1835 the results were: Damoiseau, November 4; Rosenberger, November 11; Pontécoulant, November 13; Lehmann, November 26. This time, thanks to the last shot (which is the most discordant), the target is bracketed. For the date actually assigned after the event was November 15, 1835. Rosenberger's seems to have been the most careful investigation entering into competition, and his predicted date is four days too early. It will be noted that since the last return Uranus has been added to the known list of planets, but Neptune still awaits discovery.

---

* "Newton ne nous a donné que des solutions imparfaites sur les comètes" (Lagrange).

† "The Synopsis of the Astronomy of Comets was printed off at the same time as the Tables" (Preface). This presumably means 1719, and the date of the manuscript was not later than 1717.

Before the Comet returns again, astronomy has enjoyed another period of orderly development. Thanks to Adams and Leverrier, Neptune has been included in the number of the planets, and under photographic scrutiny it seems unlikely that any other of comparable mass remains to be found. Thanks again to Leverrier and later to Newcomb, the masses of all the planets are now known with greater accuracy than before. A technical advance has been made in presenting the tabular co-ordinates of the disturbing bodies and the principles being recognized, in the calculation of special perturbations there is room for little more than a judicious choice in the management of the details. Thus the conditions for a close prediction in 1910 were favourable.

It is tempting to make one remark. The methods of science, once devised, cannot be controlled in their application. Thus the method of special perturbations, which follows the disturbed body in its motion step by step, is a form of interpolation, a method of which Newton himself was a master. But, being quite general in its character, it is essentially the same method as that employed in calculating the trajectory of a shell by small arcs, and hence the range table of a gun. It is therefore the same mathematical process which predicts the return of a comet or the course of a minor planet for the peaceful astronomer as that which gives land or naval artillery its deadly effect. This is an illustration of the simple and inescapable fact that science in itself is amoral.

In spite of the technical simplifications of which the process is capable, the task of calculating special perturbations over the three-quarters of a century (or rather over a century and a half, for two circuits of the course before 1910 were in fact followed, to ensure accuracy) is still laborious in the extreme. In this case the Lindemann Prize offered by the Astronomische Gesellschaft attracted only two competing essays, and there was no difficulty in deciding between them since one proved to assign a date two months later than the time of perihelion deduced from observation.

The successful essay was the joint work of Messrs. Cowell and Crommelin, assisted by several volunteer computers. Their date for the perihelion passage in 1910 was April 16·6. The comet was first recognized on a photograph by Dr. Max Wolf on September 11, 1909, and on March 5, 1910, the two English astronomers felt justified in stating:

> "It now appears from the observations that the predicted time [April 16·61] is 3·03 days too early. At least two days of this error must be attributed to causes other than errors of calculation or errors in the adopted positions and masses of the planets."

This very precise statement indicates that the problem of Halley's Comet has not been completely solved and ensures that the return in 1986 will receive careful attention. As in 1835 according to Rosenberger, so in 1910 the Comet reached its closest approach to the sun too late to agree with theory. As all questions of the physical nature of comets are now left to be discussed by some future Halley lecturer, this is one which needs more evidence before it can be discussed profitably. The discrepancy is of the wrong sign to be explained by the resisting medium invoked to account for the anomalous motion of Encke's Comet. On the other hand, while motions in almost parabolic orbits have had their value for the theory of gravitation, the constitution of a comet is far removed from the ideal particle which the mathematician would choose as a test. The nucleus of Halley's Comet transited the sun on May 18, 1910. By no means whatever could any certain effect be observed. Similarly, in the middle of May the earth may have passed through the tail of the comet. Whether it did so or not, no effect was to be anticipated, and certainly none was seen.

From the moment that the periodic orbit of the Comet is assured, it becomes possible to trace its course forward or backward with equal facility—or the same irksome toil. Now bright comets have appeared in the past and not a few of them have gained historical notoriety. It is therefore a question of great interest to identify such comets when possible with past appearances of Halley's Comet.

Halley himself was the first to make the attempt. The comets of 1531, 1607 and 1682 gave him intervals of 76 and 75 years. On this evidence alone a great comet should have appeared about the year 1456. It happens that a comet seen that summer, when the Turks were threatening to overrun Europe, is one of the most famous historically in the whole series. The identification in this case has proved sound. But the mean period over two milleniums is not far short of seventy-seven years, and therefore when Halley tried to go back further (to 1380 and 1305) he made errors of two and four years, and would have been led further astray if he had not stopped at that point. The method was too crude for anything more than a short-dated suggestion. The date 1456 was confirmed by Pingré (1711–1796) on the more legitimate evidence of an orbit deduced from observations.

The next identification was made by Burckhardt (1773–1825) with a comet observed in 989. Though recorded in the Saxon Chronicles, it was also observed in China, and the Chinese observations made it possible to determine an orbit.

This recognition of an isolated return illustrates the fact that the most trustworthy data before the fifteenth century are to be found in the Chinese annals. Three appearances of Halley's Comet were thus identified by Laugier (1812–1872), an astronomer of the Paris Observatory. These occurred in 451 (coinciding with the Battle of Chalons), 760 and 1378.

But the most extensive research of this kind was made by J. R. Hind (1823–1895), who, like Dr. Cowell, was later to become superintendent of the "Nautical Almanac". His work covered all the appearances of the present era from 12 B.C. onwards, and though three or four have not been substantiated, a round dozen of true identifications remain to his credit. Where he failed, the cause is simple: the Chinese observations were insufficient to establish the orbit with the necessary precision. When the

Chinese record of the Comet's return gave adequate detail, Hind was right, and Dr. Crommelin has testified to the value of his work as a foundation for subsequent research.

Thus a few doubtful cases remained, as Hind himself indicated, and to decide them a much more laborious method was required. It was necessary to trace the Comet back through the centuries by tracing its perturbations continuously. This looked like a Herculean task, and it was in fact arduous enough. But Dr. Cowell devised a notable simplification in the method and the late Dr. Crommelin and his collaborators carried out the work. Not all the refinements necessary when prediction within a few hours is aimed at are needed in this backward sweep, but no means for securing essential accuracy were neglected.

RETURNS TO PERIHELION

The result is the accompanying table, which records the times of perihelion passage over a period of two thousand years, the outcome of an investigation which is a model of its kind. With the dates are given the names of the astronomers who first identified the return with a recorded comet.

Before A.D. 1400 the identifications rest mainly on Chinese observations, as already remarked. That does not mean, of course, that the Comet was not mentioned in European annals, but merely that the European descriptions have little astronomical value. On the contrary, the Comet has blazed its trail through the pages of Western history, as in 1066, and the historian may find great interest in a list of dates which, thanks to the labours of Cowell and Crommelin, he may accept as perfectly trustworthy.

When the central problem of astronomy is considered, and the importance of Halley's Comet in relation to that problem, one thing must be understood. The history of science is no mere catalogue of ideas and discoveries. It is not enough to separate the true from the false so far as that can be done at a given time, but it is also necessary to see how the truth came to be established and how error was finally overcome. In general, the process has been slower than is commonly realized. Even in our time, when development is continuous and is watched by a thousand eyes, we have seen eminent chemists reluctant to abandon their indestructible atom and accept the electron theory of matter. It is altogether wholesome that novel assertions should meet with critical reserve.

Very different was it in the ages when science progressed by fits and starts. Thus Aristarchus of Samos, the contemporary of Archimedes, proclaimed the heliocentric theory of the solar system. Eighteen centuries elapsed before the truth of the idea was recognized by Copernicus. It is sometimes implied that this was an independent discovery. But the origin of the idea was immediately pointed out by commentators in England, and it could not have escaped Copernicus himself, who had studied in Italy and elsewhere, and was a quite exceptionally well-educated man. His merit consists in reconciling the idea with the Ptolemaic theory. But as there was nothing to prevent anyone from doing the same thing at any time during the preceding fourteen centuries, he must be held to have written a belated last chapter of the old astronomy, not a first chapter of the new. Apart from what was due to Aristarchus, the errors of Ptolemy were perpetuated.

The new order in astronomy came in 1609 with the "Astronomia Nova" of Kepler. It was the result of studying new, prolonged and more accurate observations. For the first time in a work of this kind, the proportion of truth is greater than the proportion of error. It gave a sound foundation for further progress. But how slowly was its true character recognized, even in an age which was beginning to move rapidly.

There was one notable, though unproductive, exception. It is shown in that remarkable letter addressed by Sir William Löwer from the neighbourhood of Caermarthen to Thomas Harriot at Sion House. A few sentences from it may be given:

"February 6, 1610.

"I have received the perspective Cylinder that you promised me. . . . According as you wished I have observed the Mone in all his changes. . . .

"Kepler I read diligentlie. . . . Not of his causes for I cannot phansie those magnetical natures, but about his theorie which me thinks (although I cannot yet overmaster manie of his particulars) he establisheth soundlie and as you say overthrows the circular Astronomie.

"Do you not here startle, to see every day some of your inventions taken from you; for I remember long since you told me as much, that the motions of the planets were not perfect circles. . . .

"But again to Kepler I have read him twice over cursoridlie, I read him now with Calculation. Sometimes I find a difference of minutes. . . . For this theorie I am much in love with these particulars.

"1° his permutation of the medial to the apparent motions, for it is more rational that all dimensions as of Eccentricities, apogacies, etc. . . . should depend rather of the habitude of the sun, than to the imaginarie circle of orbis annuus.

"2°. His elliptical iter planetarum, for methinks it shews a Way to the solving of the unknown walks of comets. For as his Ellipsis in the Earth's motion is more a circle[*] and in Mars is more longe and some of the other planets may be longer againe, so in thos comets that are appeard fixed the ellipsis may be neere a right line.

"3°. His phansie of ecliptica media or his via regia of the sun, even the ecliptica vera under w^{ch} the earth walkes his yeares journie; by w^{ch} he solves handsomelie the mutation of the starres latitudes. Indeed I am much delighted with his booke, but he is so tough in manie places as I cannot bite him. . . .

". . . Above al things take care of your health, keepe correspondence with Kepler and whereinsoever you can have use of me, require it with all libertie. . . .

"WILLM. LÖWER."

---

[*] What precedes this point is from a paper at Petworth House, found and reproduced by the Baron von Zach. The continuation is in the British Museum. The whole was reconstituted by Rigaud and printed in the supplement to Bradley's works. It is also to be found in Henry Stevens's "Thomas Hariot, Mathematician, Philosopher and Scholar" (London, 1904).

Three things are notable in this letter of a Welsh squire, drawing his inspiration from Harriot. First, there is the early specific mention of the use of a telescope in England. Then there is the suggestion as to the nature of cometary orbits, which is in line with, and much earlier than, Borelli's. It is to be remembered that both Harriot and Löwer observed Halley's Comet in 1607. Finally, the appreciation of Kepler and the implied criticism of Copernicus are extraordinarily acute. Such insight is nowhere to be found outside the circle of Harriot.

Why the message of Kepler fell on deaf ears elsewhere is an interesting problem. But two of the evil influences can be seen. The first—and this will surprise many who have imbibed a legend without due qualification—was Copernicus and his school. This great man had served as a useful link with the past. From the beginning of the following century the effect of his doctrines was simply mischievous. This remark can be easily illustrated.

When Horrocks started on his brief career as an observer, he sought the advice of Gellibrand, the Gresham professor of astronomy. On this recommendation he procured the works, including the Tables, of Lansberg. Comparison with his own observations soon convinced him that Lansberg was wrong in theory, wrong in everything. His denunciation of Lansberg was unsparing. Then he turned to Kepler, and in spite of the admitted faults of the Rudolfine Tables quickly came to the conclusion that he who has Kepler has everything. The tables were based on faulty numbers and these could be corrected by his own observations. But Lansberg's, being based on faulty theory, were hopelessly wrong. Now Lansberg was just an orthodox Copernican living in the wrong century; the real cause which excited the wrath and contempt of Horrocks was the Copernican doctrine, which had grown completely out of date. The work in which he champions Kepler was published thirty years after it was written, and it may have failed to have its due effect. But it is significant that all those discussions of Keplerian problems between Hooke, Wren and Halley which preceded the composition of the "Principia" were subsequent to the year 1672, when the "Opera Posthuma" of Horrocks was at last published by Wallis and warmly commended by James Gregory and by Newton.

Meanwhile Galileo had lived and died, and was destined, thanks to a few simple experiments in dynamics, to transform the thought and the physical condition of mankind. But his attitude to the problem of planetary motion is generally misrepresented. Like Harriot, he received a copy of Kepler's "Astronomia Nova", but there is not the slightest sign that he ever read it. He was not an ardent mathematician and without a Harriot at his back he was less likely to 'bite' such a book than our worthy Löwer. It is equally unlikely that he had any taste for the Ptolemaic details of Copernicus. His heliocentric theory was the simple doctrine of Aristarchus, founded on the argument from analogy which he drew from the Jovian system of satellites. As such it would be noticed as the view of a remarkable man of that age, but nothing more. That it has come to be otherwise regarded is due to quite adventitious causes, which have at the same time floated Copernicus on a tide of popular fame. These causes are the events of 1616 in the life of Galileo, the placing of the "De Revolutionibus" on the Index in the same year, and the subsequent persecution of Galileo in his declining years. But for these events, which have tended to overshadow the infinitely greater merits of Kepler, it is extremely probable that the general estimate placed on Copernicus would be slightly different from what it is to-day. Even at the time, the incidents did nothing to promote sound scientific opinion.

Altogether, astronomical opinion in the first half of the seventeenth century was in a state of great confusion. The Copernican theory still had its ardent supporters, but its radical unsoundness became more and more apparent. Instead of stimulating fresh efforts to find a better theory and to examine Kepler, as it did in the end with Horrocks, the failure induced a general feeling of futility and despair. The true system of astronomy seemed to be unattainable. On the other hand, those who had persecuted Galileo came to see that they had won a Pyrrhic victory and were ready to tolerate any theory so long as it was not called Copernican. The ground was therefore ready for a new crop, and while the good seed of Kepler was only waiting to be planted and nurtured by the hand of the mathematician, the second evil influence appeared and prepared a harvest which may have served to supersede the lingering remnants of Copernicanism, its chief recommendation in many eyes, but otherwise was worse than useless. This was the Cartesian system of philosophy.

René Des Cartes (1596–1650) spent the last twenty years or more of his life in Holland, latterly in Leyden. His chief works were two, the "Discours de la Méthode" (1637–8) and the "Principia Philosophiæ" (1644). The solid reputation of the author rests on one of three appendixes to the first. This contains his work on geometry, wherein co-ordinates are treated by algebraic methods; this is original and it marks an epoch in mathematics. Another is a treatise on optics and contains Snell's law of refraction, until then unpublished but certainly known sixteen years earlier. The science of optics, physical optics in particular, was then in a primitive state and Des Cartes did little to improve it. His later work contains his ideas on the laws of motion and his theory of vortices as a cosmic principle. To put it bluntly, this theory is trash, and it is hard to treat seriously a philosophy from which it sprang. Yet in its day, which lasted for a century, it enjoyed extraordinary popularity not only among the ignorant but also among those who would naturally be assumed to know better. Huygens, the greatest physicist of the seventeenth century, Newton not excepted, was a typical and at the same time an exceptional case. Des Cartes was an intimate personal friend of his father, Constantijn Huygens, and Christiaan was nurtured on the pure Cartesian doctrine. He remained a Cartesian through life, though this did not prevent him from correcting Des Cartes on the laws of motion or developing his own science in his own original way. But the Cartesian prejudices remained with him to the end. In England the bigger men seem to have escaped the influence tolerably well, though there was a moment when, according to Whiston, the doctrine had gained a firm hold on the teaching at Cambridge. In France the attack was most severe and lasted well into the eighteenth century in academic circles. The reason is easily conjectured. The doctrine of vortices was designed as an escape from Copernicanism to satisfy orthodox Catholic prejudices, and was therefore popular in the France of Louis XIV; besides, it was the work of a Frenchman. This explanation does not apply to the special case of Huygens, who was a Dutch Protestant, and of course the case of England is quite different. Another illustration of this line of thought is to be seen in the readiness of Voltaire to follow Newton.

It is sometimes too readily supposed that Newton's "Principia" met with immediate acceptance. Newton's reputation as a mathematician was great and had spread far beyond the limits of England. The book was recognized as a remarkable work in the limited circle of men who could read it intelligently. But if anyone thinks that its doctrines and its spirit was accepted even by the most competent judges of the time, he should read the letters which passed between Leibniz and Huygens. A few specimens may be quoted.

The first extract shows the eagerness of Huygens to see the "Principia", though he cannot conceal his Cartesian predilections. In the second, Huygens gives Leibniz excellent advice and seems to show signs of conversion; "besides, you know, these vortices are not without their difficulties". Then in the third he swings completely round: "Newton's principle of attraction seems to me absurd". Finally there is a fair sample of the obstinacy with which Leibniz clings to his Cartesian ideas. Let it be observed that, throughout, neither Huygens, the physicist who had first seen Saturn's ring with an understanding eye, nor Leibniz, the mathematician and philosopher, betrays the slightest sense of the needs of practical astronomy. The astronomer wants the "Nautical Almanac", and naturally has little patience with the philosopher who is so imprudent as to stand in the way of that legitimate object.

(*a*) Huygens to Fatio de Duillier (extract).
1687, July 1/11.

"Je souhaite de voir le livre de Newton. Je veux bien qu'il ne soit pas Cartesien pourveu qu'il ne nous fasse pas de suppositions comme celle de l'attraction.

"Cela me paroit assez étrange que les rayons employent un temps egal et qu'il ait pourtant un autre principe. La proposition du Globe assez paradoxe j'en voudrois voir la demonstration. . . .

"Mes respects a M. Boyle. Ayons le livre de Newton". ("Œuvres Complètes de Christiaan Huygens", 9, 190.)

(*b*) Huygens to Leibniz (extract).
Jan. 30.
1690, Feb. 9.

". . . Je vois que vous vous estes encore rencontré avec luy en ce qui regarde la cause naturelle des chemins Elliptiques des Planetes mais comme en traitant cette matière vous n'aviez encore vû qu'un extrait de son livre et non pas le livre mesme, je voudrois bien sçavoir si du depuis vous n'avez rien changé à vostre Theorie, parce que vous y faites entrer les Tourbillons de Mr. des Cartes, qui à mon avis sont superflus, si on admet le Systeme de Mr. Newton où le mouvement des Planetes s'explique par la pesanteur vers le Soleil et la *vis centrifuga*, qui se contrebalancent. Outre que ces Tourbillons Cartesiens faisoient naitre plusieurs difficultés, comme vous verrez par mes remarques et mesme sans elles vous ne pouviez pas l'ignorer. . . ." (Œuvres Complètes, 9, 366.)

(*c*) Huygens to Leibniz (extract).
1690, Nov. 8/18.

"Pour ce qui est de la Cause du Reflus que donne M. Newton, je ne m'en contente nullement, ni de toutes ses autres Theories qu'il bastit sur son Principe d'attraction, qui me paroit absurde, ainsi que je l'ay desia temoigné dans l'Addition au Discours de la Pesanteur. Et je me suis souvent etonné, comment il s'est pu donner la peine de faire tant de recherches et de calculs difficiles, qui n'ont pour fondement que ce mesme principe. Je m'accomode beaucoup mieux de son Explication des Cometes et de leur queues; et quoyque la chose ne soit pas sans cette grande difficultè, que vous remarquez fort bien, je ne trouve encore rien de meilleur que ce qu'il en dit, qui vaut mieux incomparablement, que ce qu'en a imaginé des Cartes. . . ." (Œuvres Complètes, 9, 536.)

(*d*) Leibniz to Huygens (extract).
1692, Sept. 16/26.

". . . Il faudra examiner quelle explication est la meilleure, ou si on les peut concilier. Le même se peut dire à l'égard de l'explication de Mons. Neuton des ellipses. Les Planetes se meuvent comme s'il n'y avoit qu'un mouvement de trajection ou de propre direction joint à la pesanteur à ce que Mons. Neuton a remarqué. Cependant ils se meuvent aussi, tout comme s'ils estoient deferés tranquillement par une matière dont la circulation y soit harmonique; et il semble qu'il y a une conspiration de cette circulation avec la propre direction de la Planete. Et la raison qui fait que je ne me repens pas encor de la matière deferente, depuis que j'ay appris l'explication de Mr. Neuton, est entre autres, que je voy toutes les Planetes aller à peu près d'un même costé, et dans une même region, ce qui se remarque encor à l'égard des petites Planetes de Jupiter et de Saturne. Au lieu que sans la matière deferante commune rien n'empescheroit les Planetes d'aller en tous sens. . . ."
(Œuvres Complètes, 10, 316.)

The views of Locke and Leibniz make an interesting contrast. Thus Locke:

"It is true, I say, 'that bodies operate by impulse, and nothing else.' And so I thought when I writ it, and can yet conceive no other way of their operation. But I am since convinced by the judicious Mr. Newton's incomparable book, that it is too bold a presumption to limit God's power, in this point, by my narrow conceptions. The gravitation of matter towards matter, by ways inconceivable to me, is not only a demonstration that God can, if he pleases, put into bodies powers and ways of operation, above what can be derived from our idea of body or can be explained by what we know of matter, but also an unquestionable and everywhere visible instance, that he has done so." ("Essay", p. 408, 1699.)

Locke also remarked that nothing is more likely to assist the sceptics than to deny what we do not understand. In his "New Essays" (1700, pub. 1765) Leibniz replies: "I fully recognize that it is not allowable to deny what we do not understand, but I add that we have the right to deny (in the order of nature at least) what is absolutely unintelligible and inexplicable."

After that exhibition of considerable egotism, is it strange that science should find in seventeenth century philosophy, the philosophy of Des Cartes, Malebranche, Spinoza and Leibniz, with all their differences, nothing much better than an obstructive irrelevancy? That is what Newton found it in the criticism of his theory of colours, and it is to be seen again in the reception accorded to the "Principia". Though the fact has been overlooked, the feeling engendered at the time will help to explain the venom which entered into the controversy over the development of the infinitesimal calculus. In his last shaft, Leibniz virtually accuses Newton of atheism, than which at the time no insinuation could be more injurious. In liberality (and perhaps in clearness) of thought the lapse of a century shows remarkably little advance on the Inquisition which condemned Galileo.

Now all this seems very far removed from the story of Halley's Comet. The object has been to show by examples drawn from the history of astronomy that the acceptance of new and sound ideas is in general slow, and that the reception of Newton's "Principia" was no exception to the rule. It remains to be seen what bearing Halley's work on comets had on the outcome.

It has already been shown, and it is generally appreciated, that Halley's share in the production of the "Principia" was a considerable and quite possibly a vital one. In the first place, he directed Newton's attention with persuasive urgency to the great problem of astronomy. But when Newton's interest had been definitely engaged in the desired direction, circumstances arose which in a man of such delicate susceptibilities might easily have turned him from the completion of his task. Halley intervened and smoothed away the difficulties as they arose. At last the work was finished and safely delivered to the Royal Society. The Society was willing and eager to publish it, but at the moment it lacked the means. Halley, then a poor man, came forward and undertook the financial responsibility. But Halley also rendered a fourth service, and the nature of this is still to be seen.

The miracle of the "Principia" lies in its comprehensiveness. At the beginning Newton had perhaps a few fundamental theories, but even of these it was necessary to recover the proofs. From this point, within a period of barely two years, he has covered the whole field of gravitational astronomy, and that in considerable detail. The first steps have been taken in the lunar theory, the most difficult part and the one which ultimately supplies the most delicate test of the whole. Nutation* has been discussed, even before its discovery from observations by Bradley. The theory of tides has been developed; the attitude of Huygens to it has been noticed incidentally. A later event may also be noted. In 1740 the Paris Academy of Sciences proposed the subject of tides for competition. The three memoirs submitted respectively by Euler, by Maclaurin and by Daniel Bernoulli are all based on Newtonian principles. Yet even at so late a date as this there was a fourth which still maintained the Cartesian doctrine and commanded respect. The pleasantest aspect of this affair was the contribution of Daniel Bernoulli, for he was the son of John who, during the controversy over the "Commercium Epistolicum" was currying favour with Newton and at the same time stabbling him in the back, and the nephew of James, who in spite of his great gifts had strange ideas about comets.

But in spite of all those things in the "Principia" which excite wonder to-day, recognition of its fundamental truth was slow in coming. Nor is this altogether surprising, because it had to wait for that confirmation which rests on the comparison of its rapidly sketched theory with the result of accurate observations. This ultimate test came in time, and in spite of small discrepancies still outstanding, the main position is no longer in dispute. But this is a result of slow growth. First Bradley introduced a new order of accuracy into the observations. Then the theory of the planets was developed. But even after a century or more, even to-day, though the margin of uncertainty grows smaller, the normal difference between observation and calculation can rarely be traced to its source with perfect assurance. There is the error inherent in the observation. There is error in the system of numerical data adopted. There is possible error and always incompleteness in the practical development of the theory. There is the possibility of unknown and unsuspected disturbing influences of an alien kind. All these must be taken into account and assessed before judgment can be passed on the adequacy or failure of the general law of gravitation.

Therefore it is not surprising that at a time when the technical state of astronomy was still backward, the sceptics could find plausible excuses for their attitude. What was wanted to overcome the opposition of the Cassinis, who were practical astronomers, and the Bernoullis, who were not, was an example, preferably qualitative and if possible spectacular, to serve as an advertisement of the new system. By his "Synopsis Astronomiae Cometicæ" Halley supplied this want. Comets had always been unruly and erratic members among the heavenly bodies. In Kepler's day, though he understood them very imperfectly, they had destroyed the lingering remnants of the planetary spheres. By reducing them to order according to Newtonian principles Halley smashed the last traces of the Cartesian vortices, which had never explained anything because they were themselves without explanation. Hence the importance of the challenge to the Cartesians already quoted, which shows that he realized clearly the significance of what he had done, though these barbed words were only published thirty-five years after they were written. By that time the issue was no longer in doubt. But one thing remained to be seen, though not by Halley: the return of the famous Comet. It was first detected on Christmas Day, 1758, when approaching the sun. How it passed on in ts appointed track has been related. With it as it went once more into obscurity went also the last remnants† of that type of natural philosophy which is associated with the names of Des Cartes and Leibniz. In hastening that day, Halley rendered his fourth great service alike to Newton and to science.

NOTE

There is an interesting passage in Whiston's memoirs[5]:

"I proceed now in my own history. After I had taken Holy Orders, I returned to the College, and went on with my own Studies there, particularly in Mathematicks, and the *Cartesian* Philosophy; which was alone in Vogue with us at that Time. But it was not long before I, with immense Pains, but no Assistance, set myself with the utmost Zeal to the Study of Sir *Isaac Newton's* wonderful Discoveries in his *Philosophiæ Naturalis Principia Mathematica*, one or two of which Lectures I had heard him read in the publick Schools, though I understood them not at all at that Time. . . . We at *Cambridge*, poor Wretches, were ignominiously studying the fictitious Hypotheses of the *Cartesian*, which Sir *Isaac Newton* had also himself done formerly, as I have heard him say. What the Occasion of Sir *Isaac Newton's* leaving the *Cartesian* Philosophy, and of discovering his amazing Theory of Gravity was, I have heard him long ago, soon after my first Acquaintance with him, which was 1694, thus relate, . . ."

---

* It must be allowed that Newton's nutation and Bradley's are not quite the same thing.

† Fontenelle, reputed the last Cartesian of any scientific standing, had died in 1757, thirty-three days short of his hundredth birthday.

Then follows an account of incidents during Newton's life at Woolsthorpe when he retired from Cambridge owing to the plague. Doubt has been cast on some details of this story. But it is corroborated in all essentials not only by Pemberton but also by an account left by Newton himself. There can be no doubt that it represents a story which Newton was rather fond of telling in his old age. If therefore any doubt is to be entertained as to its accuracy, that must be attributed to the failing memory of an old man. It does not seem impossible that some picturesque details have accrued in the course of years.

That is not the present point of interest. If according to this account Newton ever flirted with the Cartesian philosophy, that must have been during his undergraduate days. That at some time Newton must have studied "the fictitious Hypotheses of the Cartesian" is one of Whiston's essays in the obvious. As the protagonist of a system of natural philosophy which found its greatest obstacle in the hypotheses of Des Cartes, Newton could scarcely have failed to do so. But the attitude of complete antagonism was established at least as early as 1666 (*aet.* 23).

But Whiston was twenty-five years younger than Newton, whom he succeeded in the Lucasian chair at Cambridge in 1703. The year in which he took deacon's orders was 1693. Thus the years of which he is speaking, when the Cartesian philosophy was alone in vogue at Cambridge, was at least six years after the publication of the "Principia", and not very long before Newton left Cambridge for London. It appears then that whatever impression the "Principia" may have created outside Cambridge, inside Cambridge the teaching of Newton had been practically without any effect whatever.

At no time had Newton a gift for friendship. But that in itself is no reason why he should not have enjoyed the active support of discerning men. This he had, from Halley in the greatest measure, but also from others. David Gregory (nephew of James), the Savilian professor of astronomy, adopted the Newtonian philosophy from the first. When the controversy with Leibniz assumed an unpleasant aspect, it was to John Keill, another Savilian professor, that Newton turned as his champion. Locke wrote: "I have several reasons to think him truly my friend". Now all these were Oxford men. Even Henry Pemberton, the editor of the third edition of the "Principia", was introduced to Newton by Keill; he was not a Cambridge man. Robert Boyle, another acquaintance in correspondence with Newton, was a member of the group of men living in Oxford who founded the Royal Society.

It is inevitable that a comparison should be made with Newton's environment at Cambridge. If Newton sought no friends, it would still be supposed that some men of parts would seek his intellectual acquaintance. There is little evidence of it. Barrow resigned the Lucasian professorship in favour of Newton in 1669, became Master of Trinity in 1673, and died in 1677. That must have been a great loss to Newton. Whiston (of Clare Hall) made his acquaintance as related by himself, and Bentley cultivated it too, but philosophy rather than science was the common bond. This was only a few years before Newton left Cambridge; when Bentley became Master of Trinity (1700), Newton was established in London. But Bentley's account of the state of the College proves that Newton must have found it an utterly uncongenial environment. The impact of the Restoration on an academic community had been disastrous. At the same time Whiston's evidence goes to show that Newton was out of sympathy with the general trend of thought in the University of Cambridge at large.

These circumstances seem to explain much; why, for example, Newton was so ready to leave his quiet academic seclusion for the crowded life of the metropolis. It is just possible that Trinity was not so very quiet, while London and the Royal Society offered intellectual society far more to his taste. There is another aspect of the matter. In spite of Bentley's reforming zeal, which did produce fruit in a notable band of scholars, such as Porson, Cambridge in the eighteenth century, and Oxford too for that matter, failed conspicuously to take advantage of the opportunities opened up by Newton. An excuse has often been found in the notation (or absence of notation) of the fluxional calculus when contrasted with the methods of Leibniz. This seems hard to believe. Had there been a school of mathematicians, of the calibre of Colin Maclaurin for example, it is impossible to conceive that a mere question of notation would have been allowed to remain an obstacle when the successes of Clairaut and Euler were fairly considered. They did not receive this consideration because the men capable of giving it did not exist. The best English mathematicians of the period, like Simpson, Hutton and Peter Barlow, who were all connected with the Military Academy at Woolwich, owed nothing to university education.

SOME BIOLOGICAL DISCOVERIES OF PRACTICAL IMPORTANCE*

By Dr. C. H. WADDINGTON

THERE are two main spheres in which biology is of practical importance to society. One is medicine in the widest sense, which it would perhaps be more accurate to call human biology, and the other is food production or agriculture, also in the widest sense.

I do not propose to discuss the first of these fields in any detail, although new discoveries and new applications of old discoveries are always being made. Among recent new discoveries one may perhaps mention the bacteriocidal and bacteriostatic substances which are now being obtained from lower organisms. Penicillin, extracted from a mould related to the ordinary bread mould, is being investigated at Oxford and elsewhere and seems likely to prove one of the most powerful aids in dealing with infected wounds, a matter of the greatest importance at the present time. It may, however, be rivalled by gramicidin, a substance prepared by American workers from certain types of bacteria which grow in soil; but perhaps the more optimistic view will prove justified and the two substances be found to attack rather different kinds of germs and thus to supplement each other. As an example of a new technique of utilizing old biological knowledge, one may mention the treatment of various diseases, chiefly cancer in some of its forms, by radioactive substances artificially prepared with the aid of new physical apparatus such as the cyclotron. Radiophosphorus and radio-iodine are differentially absorbed by different tissues in the body; their radioactivity causes the destruction of the tissues in which they become located and the surgeon can in this way bring about a localized inhibition of particular tissues which are proliferating too rapidly.

---

* Substance of a lecture delivered at the Royal Institution on February 12.

But the great tasks of medicine in the immediate future are concerned with the application of knowledge which we already possess. These tasks can be summarized under three heads: first, the attainment in practice of optimal standards of nutrition, of housing, of industrial hygiene, and so on; secondly, the conquest of tropical diseases and the improvement of the health of tropical populations until they have an equal chance with the peoples of the temperate zones to play their part in world civilization; and thirdly, a task in which social biology must collaborate with political and other agencies, is the reversing of the general fall in the reproductive-rate in industrial countries. New discoveries may, and very probably will, be made which will assist in the carrying out of these tasks, but the main problems are certainly the administrative and political ones of applying existing knowledge.

When we turn to the field of food production we find a great body of existing knowledge which is in process of being put into practice. Such developments of farming practice as the system of ley-farming and the increased use of silage are examples. But there are also a number of biological discoveries which may have very revolutionary effects on the whole of our food production system, and it is primarily a summary of these more far-reaching possibilities that I propose to discuss.

We may mention first some new uses for old crops. Straw is bound to be produced in large quantities along with any cereal crop, but, except for some oat straws, it is itself of little value for feeding animals. It has recently been shown that a treatment with caustic alkali breaks down the hard tissues of the straw sufficiently to allow of its being digested by cattle, and a very considerable new source of feeding-stuffs has thus been placed at the farmer's disposal. A more striking innovation would be the direct use of grass protein for human consumption. Grass is much our biggest crop; we produce about 60 million tons a year. It is too full of indigestible fibre to be eaten by man in the raw state, and the methods by which we use it are still those which were invented in the Stone Age; we feed it to cattle and sheep and ourselves eat the beef, mutton, milk, etc., which they produce. They can, it is true, digest the fibres with which the human intestines cannot deal, but they are relatively inefficient in making use of the proteins. Now it is comparatively easy to grind up the grass and squeeze out some 30 per cent of the protein for our direct use. The remainder of the protein remains with the fibres, the whole mass still representing a better cattle food than ordinary hay. The technical problem of making the grass protein into a really attractive and palatable product should not long remain beyond the capacities of our biochemists. When it is pointed out that the total quantity of grass protein grown in Great Britain is something like ten times our normal protein requirements, the potential importance of the direct utilization of even a small fraction of it requires no further emphasis; but the economic and agricultural problems of employing the process on a large scale require further study.

Let us consider now some new technical possibilities in the cultivation of our crops. Much publicity has been given recently to tank-culture or hydroponics. By this is meant the cultivation of plants in culture solutions the concentration and composition of which can be accurately controlled. Such methods are, of course, by no means innovations in the laboratory; it is only their utilization on a large scale for commercially grown greenhouse crops which would be a new departure. It does not, however, seem by any means certain that this technique has any great advantages, at least in the climate of Great Britain, over the method of soil sterilization which was introduced some years ago and is now becoming very widespread.

Another technical innovation from which much can be expected is the use of the recently discovered plant hormones. Knowledge in this field is still growing rapidly but we already understand something of the part played in the growth of a plant by very small quantities of certain essential substances, some of which are in fact identical with the vitamins which we hear so much about in our own diet. Some of the hormones are already quite widely employed to encourage the rooting of cuttings; but there are many more possibilities emerging in the laboratories of the world—for example, the growing of long-fibred stems in textile plants such as flax and hemp, the production of seedless fruits from unpollinated flowers treated with suitable hormones, the control of the opening of flower buds until the danger of severe frost is past, and so on. Moreover, new hormones are still being discovered, some, such as a new pollen extract recently described by the United States Department of Agriculture, controlling growth, while others are concerned with various other phases of a plant's development.

These studies have not yet been brought into relation, although they soon must be, with another very important development which has arisen in practical crop management. Russian biologists in particular have devoted great attention to the investigation of the time of ripening of plants, with the view of developing types which can either survive their rigorous winter or which can crop in a single year after planting in the spring. They have developed a rather elaborate theory of the succession of various phases in a plant's development, which they distinguish sharply from its growth. In general a plant first passes through a temperature phase, in which it requires a certain length of exposure to particular low or high temperatures; this, they claim, is succeeded by a light phase, in which the plant must be subjected to particular conditions of long or short daily periods of illumination. The practical application and indeed the practical basis of this theory is the technique known as vernalization, in which the germinated seeds are artificially given the treatment needed to complete the first phase of development before being sown. Thus a winter variety of wheat, which is normally sown in autumn and lies in the ground over winter, starting to grow in the following spring, may be artificially cooled for the required time and then planted in the spring to crop in the same year. Such methods would be of some value even in England and may be of very great importance in countries with the severe climatic conditions of Soviet Russia, where many million acres have been sown with vernalized seeds. Workers in other countries are not so convinced of the practical value of the method, and the details of both theory and practice are still under discussion. But there seems little doubt that the basic phenomena are quite real and that our understanding of the matter will rapidly become much more profound. It has already been shown that, in certain plants, substances capable of diffusing from a stock into a grafted scion are concerned in controlling whether flowering takes place in the first or second year, that is, with or without subjection to cold and short daylight, and it therefore seems most probable that the whole vernalization question will in time be brought into relation with the discovery of plant hormones already mentioned.

Some Soviet authors have claimed that a single vernalization treatment is sufficient to alter the hereditary constitution of the plants, so that its effects are permanent. Most biologists are likely to doubt the possibility of such a direct action, but it may well be that the Soviet workers have actually discovered a phenomenon of great importance. Since the development of a plant, as we have seen, is profoundly influenced by the early treatment of the seed, a single artificial treatment which causes the plant to mature at an abnormal season may have some effect on future generations owing to the altered conditions under which the seed will be formed. Similarly, another phenomenon on which the Russian scientific workers have laid great stress is the effect of a host plant on the hereditary constitution of a graft; again, the effect may not be a direct one on the hereditary elements as normally understood, but it may be a real phenomenon based on the transmission of something in the nature of a virus.

This brings us to the subject of plant-breeding, one of the fields in which the most spectacular advances are likely in the near future. The breeding of disease-resistant varieties, which, for example, trebled the yield of sugar cane in Louisiana between 1926 and 1929, will probably score some new successes but it cannot be considered a new technical advance. On the other hand, the practical employment of hybrid vigour is a development of the last few years in maize growing. At the present time something like twenty-five million acres are sown with hybrid corn in America, and increases in yield average about 20 per cent. Probably there are similar benefits to be obtained in other crops. The John Innes Horticultural Institution, for example, has prepared hybrid tomato seed with very considerably enhanced productivity.

The most important advances, however, are likely to come from two fields which are still being intensively investigated. The first is the study of the wealth of forms available in Nature for our use. Until recently the range of types employed by the plant breeder has been getting progressively narrower as he concentrated on the improvement of ever more specialized varieties. But it has been realized that much may be gained by the introduction of new hereditary material and it has come as something of a shock to discover how rich is the stock of forms available. Not only are there very numerous local varieties of cultivated plants, each probably with many defects by modern standards although with one or two points of advantage, but there is also a hitherto unexpected variety of wild forms related to the cultivated species. For example, all the cultivated potatoes of the Old World derive from a single species and probably from a very few individuals. We know now at least thirty species, forming a polyploid series, all of which were thought worthy of cultivation by some tribe in South America, and there are also related wild species. They include frost-resistant and short-day forms and varieties resistant to various diseases. It is not too much to hope that we shall fairly soon be able to develop potatoes suitable for the Arctic and for the tropics. The profound results of such a spread of the potato belt do not need to be emphasized.

The second major source of new varieties may be found in the very recent technique of artificially doubling the number of chromosomes in hybrids, thus rendering them fertile and comparatively stable in hereditary constitution. Nearly all our most important crop plants have arisen by a chance occurrence of a similar process in Nature. Now that we have discovered substances, the most important of which is the drug colchicine, which allow us to double chromosome numbers with fair regularity, it is almost inconceivable that we shall not be able to manufacture completely new types of plants of the greatest importance. It is too early as yet to name any examples with complete confidence, but the hybrids of wheat and rye, and of wheat and couch grass may be mentioned as instances of promising beginnings.

An advance of another kind is the recent success in hybridizing yeast. Until recently it was thought that if a single yeast cell was isolated it must give rise to a pure colony. But single yeast cells may be either haploid with one of each kind of chromosome or diploid with two. In the latter case haploid cells will be formed during the growth of the colony and the segregation of different types will occur, so that the final colony is mixed. Winge, in Denmark, has succeeded, by a fine technique of micro-manipulation, in isolating single haploid cells, hybridizing them and finally isolating the segregants from the hybrids. This is the first application of modern breeding methods to some of man's oldest plant collaborators, his assistants in the manufacture of such staples as bread and beer.

If we turn now to the animal field, many of the methods which seem to promise best among plants do not appear very feasible. Thus there are great technical difficulties in making such a full use of hybrid vigour, although some promising results have been obtained with fowls. Again, only the very first steps, in which I have myself shared, have been taken towards doubling the chromosome number in animals, and the difficulties to be surmounted before we can produce fertile hybrids in this way are rather overpowering in prospect.

Perhaps the most important new technique which is just passing from the laboratory into general practice is that of artificial insemination. If the sperm of a selected male is artificially introduced into the female, the greater degree of control over the process makes it possible to employ much smaller quantities than Nature provides, and the number of offspring which can be obtained from a single male may therefore be multiplied some hundreds of times. This makes it possible to ensure that only the very best animals are used as fathers and the constitution of poor stock may thus be quite rapidly improved. The method has already been tested out on quite a wide scale and it has been found possible to send the sperm of desirable males for very considerable distances by air. The method has a very great part to play in the immediate post-war world when we are confronted with the problem of restoring the scorched earth of eastern Europe.

A development of the technique of artificial insemination which seems likely in the next ten or twenty years is the artificial determination of sex by the separation of male- and female-determining sperm. Such a possibility is, of course, a favourite theme of all kinds of charlatanry and psuedo-science. But some recent work, particularly in the U.S.S.R., indicates a serious possibility that the problem will be solved by the method of electrophoresis, that is to say the passage of an electric current through a suspension of sperm, causing an accumulation of the female-determining sperm at the anode and of male-determining at the cathode. There are still many technical details to be worked out, such as the most favourable salt solutions, temperature, etc., but it would be a bold man who denied the possibility of a fairly early solution of the problem. The importance of such a method for the dairy and poultry industries would be profound, but its application to human affairs obviously presents aspects of great difficulty.

It would be in the highest degree desirable to bring about a similar increase in the reproductive capacities of the females of domestic animals. This may be too difficult a task, but some increase can already be envisaged. The administration of suitable hormone preparations, for example, can bring a female into the breeding condition at a time of year when she would normally not be ready to receive the male. Some success has already been achieved in obtaining in this way two crops of lambs a year instead of one. Again, when a female is ready to breed the number of ova produced, and thus the number of young born, is rather restricted in many of our domestic animals, and treatments are being worked out which should make it possible to cause the formation of more ova. This will, in the first instance, enable us to cause a regular production of twins by our beasts. For particular purposes of breeding from exceptionally favourable females it may prove possible, by a technique which has already been used in rabbits, to increase the number of ova many times and to transplant some of them to the uteri of other females, which would then act as foster-mothers from the very earliest stages of the animal's development.

The control over developmental processes given us by the use of hormones may play a part in several other ways. We are beginning to have some understanding of the role of such substances in lactation. We know there are hormones which control the initial development of the mammary glands as well as the intensity of their secretion, and again it has proved possible to influence to a significant degree the content of milk in several important constituents. All these investigations, still essentially laboratory matters, are likely fairly soon to reach the point where we can begin to apply them in practice, when they may open up great possibilities of control over our milk supply, particularly in the difficult winter months.

A somewhat more speculative possibility is the employment of hormones for the control of size. In some animals at least, for example, the rat, it has been possible to obtain considerably increased growth by suitable hormone injections. Further, the embryo of a mammal is in a somewhat similar position as regards its mother as the plant grafts mentioned earlier; an effect exerted primarily on the mother may, by influencing the early development of the fœtus, produce an alteration which will affect the development of the next generation of young and thus be transmitted potentially for ever. That such an influence of the mother on her offspring of the first generation is a possibility is known from crosses between large and small breeds of horse, in which the size of the mother has a great effect on the size of the foal. An effect in more remote generations has been suggested by some workers using extracts of the thymus gland on rats. The matter is still very uncertain, but if it can be put on a firm basis very important results might be obtained. A further and still more speculative possibility may perhaps be worth mentioning; it has been claimed that the very early administration of growth-promoting extracts has a differential effect on those organs which develop most rapidly at early stages, particularly the brain. It is not clear whether the swollen-headed rats so produced were any cleverer than usual, but the possibility of such an effect may be worth considering, if only as a day-dream to solace the despair to which most educators are from time to time reduced. Let us hope, however, that man is already intelligent enough to use, for his benefit and not only for his destruction, the gifts which science offers, without waiting for a hormonally induced enlargement of his brain.

OBITUARIES

Sir Francis Younghusband, K.C.S.I., K.C.I.E.

SIR FRANCIS YOUNGHUSBAND, whose death occurred on July 31, was an outstanding example of that rather rare combination—a philosopher and a man of action. A passionate admirer of the beauties of Nature he had, almost from childhood, pondered and studied the mystery of living things—their origin, their evolution and their spiritual significance—and during his later years he embodied his thoughts and his philosophy in a number of books and papers.

His more practical activities as a man of action found their chief outlet shortly after he arrived in India as a young officer of cavalry. His first journey, in 1886, at the age of twenty-three, was made in company with Mr. H. E. M. James of the Bombay Civil Service, and Mr. H. Fulford of the Chinese Consular Service, when they travelled through large areas of Manchuria and explored in particular the range known as the Long White Mountain. An account of this journey was given by Mr. James in his book of that name, in which he pays tribute to the energy and ability of his young companion, who made himself invaluable in a variety of activities—surveying, the collection of entomological and botanical specimens, sketching, and so on. These wanderings extended over a period of eight–nine months, and were immediately followed by Younghusband's famous journey across Central Asia from Peking to India, culminating in the crossing of the hitherto unknown Mustagh Pass into Baltistan. This journey is described in his own book "The Heart of a Continent", one of the classics of Asiatic (or indeed of any) travel, admirable alike both for the intrinsic interest of the journey itself and for the style in which the book is written. The publication of this book at once placed Younghusband in the foremost ranks of contemporary travellers and writers.

From this on his active life, both as an officer of the Indian Foreign and Political Department and as a traveller, continued almost without a pause until his retirement on pension in 1910. During the years 1888–91 he made a series of journeys through the wild areas of Central Asia, the Pamirs, Kashgaria, and certain hitherto unexplored tracts lying to the north of the Karakoram and Mustagh ranges. These journeys had a political as well as a geographical interest and importance. Later he served in Chitral, and travelled in South Africa as *The Times* correspondent just prior to the outbreak of the Boer War.

Younghusband was thus a well-known figure with a world-wide reputation when, early in 1903, he was appointed by the Viceroy, Lord Curzon, as commissioner in charge of the projected mission to Tibet, then in process of preparation on the Darjeeling frontier.

It was here that I first met him, and in the capacity of secretary and interpreter to the mission I was constantly by his side until he returned to India some sixteen months later on the conclusion of his task, and I was thus able to get to know him intimately and to appreciate his character and his capabilities. A man's character may often, I think, be estimated not so much from his conduct on the great occasions and crises of his life as from his reactions to the petty affairs of everyday and the small worries and mishaps inevitable during travel or a military expedition. Of these we had our full share during the mission—cold, fatigue, boredom, and at times danger and excitement. During all these critical months, when the chief responsibility for success or failure rested on his shoulders, I never once saw him, even for a moment, in the slightest degree flurried, impatient, cross, or in any way perturbed. He remained always cheerful and good-humoured, and apparently indifferent to the small matters which affect ordinary mortals. This was not a pose. It was an attitude of mind based upon his essential equanimity. He knew very well what he wanted and how he proposed to get it, and having thought all this out carefully he was able to relegate all minor considerations to their proper place. But at the same time when any major difficulty or danger, or difference of opinion arose which seemed likely to interfere with his plans or the progress of the mission, he was persistent, inflexible and courageous to a degree.

It was, in fact, greatly due to this combination of qualities—on one hand infinite patience where patience and conciliation appeared advisable, and on the other readiness to fight and to accept risks and responsibilities at critical moments—that our mission succeeded as it did.

It is an old story now and has often been told, but it should be remembered that it was not an easy business. The Tibetans were obstinate and pugnacious; and the dispatch of a mission with a small military escort into the depths of Asia, hundreds of miles beyond the Himalayas, and separated from its base by several lofty mountain passes and (when at Lhasa) by a great unbridged river, resembled more the adventures of Cortes or Pizarro than modern military and diplomatic procedure. There were occasions when failure seemed imminent and inevitable. But, as I have remarked above, it was the combined tact and firmness of the Commissioner which always overcame the crisis, and which eventually secured not merely a favourable treaty with the Tibetans but also the goodwill and friendship which have lasted from that day to this.

I have dwelt at some length on this Tibetan affair, partly because it is the culminating point in Younghusband's career as a man of action, and partly because it presented such an opportunity for the exercise of his peculiar qualities. He retired from the service a few years later, and during the remainder of his life devoted himself to work with the Royal Geographical Society, the organization of the Mount Everest expeditions, and to writing.

During these latter years he published a number of volumes dealing with his favourite subjects: the beauties of Nature, Indian aspirations, and philosophical musings and conclusions. Of these latter the volume which perhaps summarizes most fully the general trend of his mind is "The Living Universe", published in 1933. In this book he traces the genesis and development of this planet from fiery vapour to the present day, and he outlines his conclusions on the vexed and oft-debated question of the origin and evolution of life and intelligence from apparently dead matter. Space does not permit of any attempt to follow him in this thesis, but a perusal of the book will give a good general conception of his attitude towards such questions and the evolution of higher types of beings on this and possibly on other planets; and in some most interesting passages he reveals certain mystical experiences which have come to him.

It was during these latter years, too, that Younghusband organized the World Congress of Faiths, representing all the world's chief religions. The catholicity of his views, and the wide respect which these views commanded, were well illustrated in the memorial service held at St. Martin-in-the-Fields on August 10 when, besides the customary Christian prayers and hymns, extracts from the Hindu, Jewish, Buddhist and Moslem scriptures were read by representatives of each of these faiths.

Such a character is rare, and when his achievements as a soldier, explorer and diplomat are borne in mind, perhaps unique. His friends will always remember him with affection for his patience, tolerance, good humour, simplicity and utter sincerity.

Frederick O'Connor.

Mr. D. B. Mair

David Beveridge Mair, who died at Galashiels on July 21, was well known as a mathematician and was a distinguished member of the Civil Service. He was born in Canada on March 24, 1868. His father, who was a Presbyterian minister, of an Aberdeen family, died young. David Mair was at school at Dollar Academy. At the age of sixteen he entered the University of Edinburgh and obtained first class honours in mathematics and in natural philosophy. He went to Cambridge as a scholar of Christ's, and was second wrangler in 1891. In 1893 he was awarded a

Smith's Prize and in 1894 was elected a fellow of Christ's.

During the next two years, part of Mair's time was spent in study abroad, particularly in Germany, and part in lecturing to honours students at University College, London, under Prof. Karl Pearson. In 1896 he was appointed a junior examiner in the Civil Service Commission; from that time, although he kept up his mathematical studies (including that of relativity), he devoted almost the whole of his energy to his official work. He had a powerful and original mind and would undoubtedly have done valuable work in mathematics in the greater freedom of an academic career. However, he found adequate scope for his abilities in the many problems arising out of the work of the Commission; he became head of the examination branch in 1907 and in 1918 was also appointed an assistant commissioner.

By nature Mair was an ardent reformer; but to the zeal of a missionary he added the remorseless logic of a mathematician and the open-mindedness of a scientific investigator. His prentice hand he tried on the mathematical question papers of school standard, eliminating book work and formal questions such as "solve the equation . . .", and substituting problems, particularly those of a practical nature on matters of everyday life. All candidates were required to use mathematical instruments and in some schemes of examination, for example, Army Entrance, laboratory tests in mathematics were added. For these tests he developed a fully equipped laboratory for the simultaneous examination of a number of candidates. As opportunity arose he endeavoured to get the syllabuses changed by removing the icy hand of Euclid and cutting out dead wood. At a later date somewhat similar treatment was accorded to the examinations of higher standard. There is little doubt that his efforts had a very considerable effect in improving mathematical teaching in Great Britain.

In course of time similar ideas were applied to other subjects, such as natural science, modern languages, etc. Nothing was too small to escape his eagle eye and fertile brain. For example, he devoted much time to drafting a syllabus in handwriting and devising a scheme by which a candidate could obtain full marks for a clear workaday hand, instead of spending laborious hours in order to produce in the examination room a beautiful specimen of what was known as the "Civil Service hand"; for spelling he evolved a type of question paper on a phonetic basis, for which he designed some special symbols.

Naturally, he gave much attention to wider problems such as the drafting of schemes of examination and the adjustment of candidates' marks. As regards the latter subject, the methods used in the Commission were far in advance of those of other examining bodies; little information was published but particulars were readily given to inquirers.

In drafting schemes of examination, Mair endeavoured to bring them into close connexion with the educational system of the country, so that candidates could take the Civil Service examinations in their stride without special preparation at school or college, or recourse to a crammer. Besides the advantage to the candidate, this procedure widened the field and was thus of benefit to the State. He was also strongly in favour of selecting candidates of mature age by interview and record instead of by a written examination—the traditional Civil Service procedure. Further, he was always prepared to experiment with new methods, such as intelligence tests, to devise means of estimating their value, and to discard them if they proved useless.

A great impetus was given to the improvement of the examination methods of the department by the appointment of Mr. (later Sir) Stanley Leathes as first commissioner. He was a man of great ability and wide knowledge, an experienced examiner, and much interested in educational matters, particularly in the teaching of modern languages. In 1919 the Treasury set up a committee to consider the scheme of examination for Class I clerkships, the highest grade in the Civil Service, with Leathes as chairman and Mair as secretary. This Committee produced a very interesting report and recommended many important changes, including the introduction of a *viva voce* test and elementary papers in English, general knowledge, a foreign language and elementary science, in addition to advanced papers in the candidates' special subjects. The scheme, with certain variations, was adopted for the whole administrative group, namely, Class I clerkships, appointments in the Indian Civil Service, Foreign Office clerkships, etc.

During the War of 1914–18, Mair assisted Sir Alfred Ewing in the Intelligence Department of the Admiralty in deciphering intercepted German code messages. In 1921 he went to India to preside at the first examination held in that country for appointments to the Indian Civil Service.

Mair retired from the Civil Service in 1933 on reaching the age limit, and since then spent much time travelling abroad. He was a singularly modest man and never courted publicity. Small of stature but stoutly built, he was of impressive appearance; he had a piercing and very intelligent eye, a clear resonant voice, and a strong chin. He held decided views on most subjects and was always prepared to express them, and, if need be, to throw them overboard. He possessed a dry humour, well under control.

His publications included an elementary text-book on mathematics and one on fourfold geometry. He married in 1897 Jessy, daughter of Mr. William Philip. She survives him with a son and three daughters. Mrs. Mair was for many years secretary of the London School of Economics, and their eldest daughter is Dr. Lucy Mair, well known as an anthropologist.

LENNARD BLAIKIE.

WE regret to announce the following deaths:

Prof. Kurt Brandenburg, professor of special pathology and therapy in the University of Berlin, editor of the *Medizinische Klinik*, aged seventy-three.

Dr. W. A. Bryan, director of the Los Angeles Museum of History, Science and Art, on June 18, aged sixty-six.

Prof. A. Döderlein, formerly professor of gynæcology and obstetrics in the University of Munich, a pioneer in the bacteriology of the puerperium, aged eighty-one.

Dr. Laurence S. Moyer, of the Department of Botany, University of Minnesota, known for his work on the biochemistry and physiology of plants.

Prof. Francis Ramaley, emeritus professor of biology in the University of Colorado, botanical editor of *Ecology*, on June 10, aged seventy-one.

Sir Montagu Sharpe, K.C., the well-known ornithologist, chairman of the Council of the Royal Society for the Protection of Birds, on August 23, aged eighty-five.

NEWS and VIEWS

H.R.H. The Duke of Kent, K.G., P.C., K.T.

It is with deep regret that we record the death of H.R.H. The Duke of Kent on active service in a flying-boat crash in Scotland on August 25. The Duke was thirty-nine years of age. For ten years, as Prince George, he served in the Royal Navy, and it was not until he was withdrawn from active service with the Navy that his talents and capabilities for public service could be thoroughly appreciated. As president of St. George's Hospital, he took a great personal interest in its welfare and prosperity. At the age of twenty-six he joined the Foreign Office and later moved to the Home Office, where he did important work in the inspection of factories and in other problems of sociological interest. His keenness for this work inspired him to sever his official connexion with the Home Office and to study industrial problems at first hand. His prolonged tour of the industrial north in 1931, followed by a series of less formal visits to factories and workshops, will long be remembered.

Sir Harold Scott, K.C.M.G.

Sir Harold Scott, who retires from the post of director of the Bureau of Hygiene and Tropical Diseases on August 31, has made notable additions to our knowledge of tropical medicine and comparative pathology. In Jamaica, when Government bacteriologist, he elucidated the problem of the so-called 'vomiting sickness', proving it to be due to poisoning by the ackee fruit (*Blighia sapida*), a common native food on the island, wholesome when ripe and naturally opened, but highly toxic in its unripe, unopened condition. He also investigated another baffling disease in Jamaica, showing it to be a 'central' and not a 'peripheral' neuritis as previously thought, but of toxic origin closely allied to certain avitaminoses occurring in Africa and elsewhere. As Government bacteriologist in Hong Kong he added much to the knowledge of tuberculosis by his investigation of its prevalence and character among Chinese of the poorer classes. Later, when pathologist to the Zoological Society of London, he was able to compare his three hundred postmortem studies of fatal human cases in Hong Kong with similar studies on wild animals dying of tuberculosis in the Zoological Gardens. His results, published by the Medical Research Council in 1929, throw much light on the pathology of the disease, the portals of entry, and on the lymphatic systems in relation to paths of infection within the body.

As medical secretary of the Colonial Medical Research Committee during 1928–30, and as assistant director and then director of the Bureau of Hygiene and Tropical Diseases, Sir Harold has greatly promoted and encouraged research in the Colonies. His "History of Tropical Medicine", published in 1939 and based on his Fitzpatrick Lectures delivered before the Royal College of Physicians, is a monument of learning and exposition.

Science and the War Effort

Prof. J. D. Bernal, speaking on "Science and the War Effort" at a meeting called by the Staff Associations of the National Physical Laboratory and associated laboratories on July 28, referred to the changing role of science in warfare. The conception of the function of the scientific worker and technician at the beginning of this War, as during the War of 1914–18, was confined to dealing with such technical devices of war as were beyond the scope of Service personnel. It is, however, becoming increasingly realized that science interpenetrates war activities over the whole field, and the scientific method is becoming a general mode of approach to the whole field of military action. During the last 150 years, tradition has ruled warfare and tactical surprise has played a small part. Following the War of 1914–18 an attitude of complacency has ruled and we have not attempted to apply scientific thinking further to war problems. On the other hand, the Germans, having been defeated, have spent the intervening period in making a far-reaching and comprehensive study of the reasons underlying that defeat. It seems to be a general feature of history that a defeated nation intensifies its study of warfare, and produces surprising tactical changes. Thus the enemy has obtained an advantage in that he has built up a powerful war machine based on the scientific method. We have accordingly to set ourselves the task, not only to catch up with him, but also to surpass him quickly.

In setting ourselves to this task we have two advantages. In the first place we have not been subjected to the intensive concentration on war machines to the exclusion of other fields of scientific endeavour; and secondly, whilst German methods are undoubtedly effective, they do not lend themselves to elasticity of thought in new developments. It is here that our free and democratic methods might be turned to good account. Addressing himself to the problem of mobilizing science to speeding up the war effort, Prof. Bernal said we have to apply scientific resources to the War in a strategic way. Thus we must apply all available forces to definite ends. In the past our efforts have been somewhat unbalanced. The probable yield from any effort must become the criterion. Military affairs are such that, owing to the difficulty of changing over, unless, say, a 100 per cent yield is to be expected in a year, the work is not worth doing. There exist generally several restrictive features which must be removed if scientific work is to be fully utilized. Perhaps the greatest handicap is the lack of direct contact between scientific workers and their opposite numbers in the Services. This is often accentuated by excessive secrecy. Some bottle-necks are due to established departmental procedure and others are due to small departments which are trying to deal with a greatly increased volume of work with unexpanded staff and equipment.

The full effects of science on war cannot be felt unless the scientific mind can be brought to bear on the war as a whole. This is not only a matter for the 'higher ups' but every scientific worker has now a widened responsibility, and a revaluation of responsibility is required. This brought Prof. Bernal to his main point, that it is not sufficient merely to work harder than in peace-time. It is also necessary to examine the implications of the work and search for ways and means of expediting progress and improving organization. The person on the job is in a position where he or she can make useful suggestions in these directions, and the speed and efficiency with which we must work require of the person on the job that he does consider this to be a part of his responsibility. Here a special duty falls to the organized scientific workers, and it is now possible, without friction, to carry out the implications of this wider responsibility through joint consultation on matters affecting efficiency. In conclusion, Prof. Bernal expressed the belief that the undifferentiated way of dealing with things which is characteristic of the scientific method, will, given good organization, build up a far better war machine than the one we have against us.

The War and Nesting Birds

The most interesting effect of the War upon nesting birds in Great Britain has been the attraction of the black redstart (*Phœnicurus ochrurus gibraltariensis*) to nest in the air-raid ruins of some English towns. Until the War, this was one of the rarest British nesters, although a regular winter visitor, but on the Continent where it is a familiar town bird it shows a partiality for ruins and it would be interesting if it becomes a commoner British resident in this unexpected way. In 1923 this bird was first noted nesting in Great Britain in a southern county and in 1936 it began nesting in Cambridge. In 1940 and 1941 it nested in the city area of London and a considerable number of London Natural History Society observers watched the birds. Another influence upon nesting birds has been the military disturbance of many coastal and rural haunts, the felling of woods and the draining of marshland. Another rare British nester, the black-necked grebe (*Podiceps nigricollis nigricollis*), was under observation by the Merseyside Naturalists' Association this year at a new nesting site at Abbot's Moss, the third it has used in Cheshire. In Anglesey there was a considerable increase in the number of roseate terns nesting at Llandwyn island, where between sixty and seventy pairs nested this year with Sandwich terns, etc., and new terneries, possibly an overflow of this species, were made at Malldraeth Point and on Ynys Ferrig rocks in Rhosneigr Bay. The kite has, however, maintained its nesting haunt in the valleys of mid-Wales and the black guillemot its recent habitat on the Cumberland cliffs at St. Bees Head.

The British Association

The report of the British Association for 1942 (Vol. 2, No. 6) is now available (price 5*s*.), and contains the full text of the papers given at the conference on European agriculture held by the Division for the Social and International Relations of Science in London during March 20-21, 1942. Problems in post-war reconstruction was the subject of discussion at the conference, the papers falling into four main sections: measures for reconstruction, economic and kindred problems, the future betterment of European farming and problems of peasant farming. The contributors, many of whom came from occupied countries and represented very different types of farming, were remarkably in agreement as to the causes of pre-war agricultural problems and the main lines upon which future reconstruction should be based, namely, the development of small-scale peasant farming, concentrating primarily on live-stock, fruit and vegetable production in order to raise the standard of living and nutrition.

In addition, the report contains an article by Sir Henry Lyons on the work of the International Research Council (now the International Council of Scientific Unions) which will be of special interest to those concerned with the possibility of increasing collaboration in science through some form of standing organization, and an account of the peace-time activities of the British Association by its president, Sir Richard Gregory.

The Study of Soils

The Cantor lectures delivered at the Royal Society of Arts by Dr. B. A. Keen in January and February on soil physics, soil cultivation, and cultivation and crop yields have been published in the Society's *Journal* (**40**, 545; 1942). The study of soil physics is relatively new, and only within the last twenty or thirty years has this side of agricultural practice been placed on a sound theoretical basis. The substitution of the pore-space theory in place of the capillary-tube hypothesis as an explanation of the water relations within the soil has, for example, led indirectly to improvements in certain practices in irrigation areas and in land drainage. The effectiveness of different types of cultivation and the influence of weather on the formation of tilth can now be measured by studying the resulting soil structure, and both the design, performance and use of implements can accordingly be put on a more scientific basis. As regards the effect of cultivation on crop yield, the traditional views held in Great Britain are called in question. Experiments on certain soils have shown no special benefits to the crop from additional or increased depth of cultivation, and since cheap labour is no longer available and every mechanized operation costs fuel and oil, a plea is made for similar investigations to be carried out in widely different districts, so that reliable information of a more general nature on such an important economic question may be forthcoming.

Canadian Water Supplies

Eight years ago the Canadian Department of Mines and Reservoirs began a survey of all the water supplies in Canada, with the view of determining the mineral and other content of the industrial and domestic water of the Dominion. The final results of this survey are now published in "Industrial Waters of Canada", by H. A. Leverin (Ottawa: King's Printer. Pp. 112. 25 cents). The investigation involved the determination of suspended matter, silica, iron, calcium, magnesium, sulphate, alkalis, potassium, bicarbonate, free carbonic acid, chloride, nitrate, oxygen, hydrogen-ion and colour. The report discusses the origin and distribution of these impurities and their importance in many industrial processes. It appears that distilled water is necessary not only in the manufacture of chemicals or drugs but also in the manufacture of ice, storage batteries, yeast, aerated waters and the plating of mirrors. In the paper and pulp industry, in the making of such varied commodities as textiles, soap and ice, and in brewing, distilling, baking, tanning, canning, etc., the nature and amount of the impurities are of much significance. The processes used in the investigations are fully described, and the publication contains tabulated analyses of surface and civic water supplies and maps showing the hardness of town water supplies throughout the Dominion.

Tuberculosis in El Salvador

The March issue of the *Boletin de la Oficina Sanitaria Panamericana* contains an interesting paper by Dr. Rafael Vega Gomez, head of the Tuberculosis Department and ex-director of health, El Salvador, on the control of tuberculosis in his country. The campaign against the disease began in 1928 with the foundation of a National Tuberculosis Sanitorium, in which the number of beds has risen from 30 to 105. Previously the only accommodation for tuberculosis were some rooms in the Hospital Rosales of El Salvador. In 1931 the local Red Cross opened the first public dispensary and founded the National Anti-tuberculosis League. Five years later another dispensary was opened at Santa Ana. In 1939 the director of health created a Department of Tuberculosis and in 1940 opened a new dispensary where 14,000 examinations were made and 93 per cent of the contacts were investigated, while 5,000 homes were visited. In 1938 the first census was taken to determine the amount of infections among school children in the capital; 4,151 were examined. The Montoux and Pirquet tests were found to be positive in 32·8 per cent of the five to six year olds, and in 62 per cent of those aged 14–15. Similar results were obtained in Santa Ana in 1939. Of 12,000 apparently healthy persons at El Salvador in a population of 100,000, 1·42 per cent showed signs of active tuberculosis. Recent figures showed a distribution of 22 per cent, 64 per cent and 14 per cent among the minimal, moderate and advanced lesions respectively, which are very encouraging figures compared with those of 1932, when about 72 per cent of the cases showed advanced lesions.

Suppressing High-Frequency Disturbances from Telephone Apparatus

In an article by M. E. Krom (*Bell Lab. Rec.*, 20, No. 10, June 1942) it is pointed out that disturbances such as those arising from the opening of the contacts of a telephone dial may be represented by an infinite number of alternating currents extending upwards through the entire radio spectrum. Disturbances of this type may reach receivers by direct radiation, by coupling between the telephone line and receiving antenna, or by secondary coupling via some outside electrical system such as a power line. Two general types of suppression devices are available to limit noise influence. One, located at the source, tends to reduce the radio-frequency voltages developed; the other—usually remote from the source—is functionally a low pass filter. The former type most commonly consists of a small inductance and capacitance connected across the dial contacts. The inductance prevents too rapid a build-up of current as the contacts close whilst the capacitance reduces the voltage on the telephone line as they open.

The filter action results in the voltage increasing slowly as the contacts open, instead of producing a series of high-frequency surges, and 40–55 db. suppression is obtained. Another type of filter similar in action but of different characteristics, is used to suppress radio-frequency voltages from teleprinters and affords some 50–60 db. suppression over the range of from 200–30,000 kc. The disturbances from power plant associated with telephone equipment are usually effectively suppressed (20–25 db.) by simple condensers. Where the individual sources of noise are numerous the second general type of device—the low pass filter—is used, and it may consist of an inductance connected in series with each side of the line, the outgoing ends of which are terminated by a condenser connected to earth. It is desirable that inductive elements used in radio filters have a high effective resistance over a wide band of frequencies instead of a peaked impedance at the resonant frequency.

Man-Made Radio Interference

An article by R. A. Shetzline (*Bell Lab. Rec.*, 20, No. 10, June 1942) reviews the factors involved in this increasingly important subject. Opening with a brief reference to the multi-frequency disturbances caused by the operation of a relay or switch, the author cites an example of a telephone line and an adjacent power line as a source of interference to a nearby radio receiver. Attention is directed to the signal-to-noise ratio of a receiver as the criterion of its performance, and it is shown how this ratio is dependent on the field intensity of the received radio signal and on the effectiveness of the antenna, the latter being a function of the effective height of the antenna and the impedance relations between antenna and receiver.

Expressions are evolved from which it becomes apparent that the best radio reception is obtained when the field intensity, antenna efficiency, line coupling loss and the attenuation along the line are greatest; the latter depends upon whether the line be cable or open wire. Interference by direct radiation becomes of importance only when the source is close to the antenna or on the same premises as the receiver. Experience has shown that in many instances noisy reception reports arise only when distant stations are sought. With field strengths of reasonable values, and with suitable antenna circuits, simple preventive measures should mitigate the annoyance caused to radio listeners by telephone apparatus.

The Night Sky in September

The moon is new on September 10d. 15h. 53m. U.T. and full on September 24d. 14h. 34m. The following conjunctions will occur during the month: Sept. 2d. 20h., Saturn in conjunction with the moon, Saturn 3° N.; Sept. 6d. 00h., Jupiter in conjunction with the moon, Jupiter 4° N.; Sept. 9d. 05h., Venus in conjunction with the moon, Venus 2° N.; Sept. 9d. 15h., Venus in conjunction with Regulus, Venus 0·7° N.; Sept. 12d. 15h., Mercury in conjunction with the moon, Mercury 6° S.; Sept. 30d. 05h., Saturn in conjunction with the moon, Saturn 3° N. Mercury, in greatest elongation, 27°, on Sept. 15, is an evening star and unfavourably placed for observation for northern observers. Venus is a morning star, and Jupiter in Gemini is well placed for observation in the morning. Saturn and Uranus are not very far from Aldebaran and appear in the east before midnight. No occultations of any bright stars will occur during the month. The longer evenings provide an opportunity for seeing many interesting sights such as the Pleiades, the variable star Algol, the Great Nebula of Andromeda close to the star ν Andromedæ, and other objects of interest.

There will be a partial eclipse of the sun on Sept. 10, visible at Greenwich. The circumstances of the eclipse at Greenwich are as follows:

Magnitude	Eclipse begins	Greatest phase	Eclipse ends
0·33	15h. 24m.	16h. 17m.	17h. 07m.

Announcements

Sir Henry Dale, who was recently appointed a member of the Governing Body of the Lister Institute of Preventive Medicine, has been elected by the Board as its chairman.

An open meeting of the Association of Scientific Workers will be held on September 4 at 7 p.m. at the Caxton Hall, London, S.W.1, to discuss and support proposals for a Central Scientific and Technical Board. The speakers will include Lord Strabolgi.

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Non-effect of Massive Doses of Progesterone and Desoxycorticosterone on Lactation

UNTIL recently, progesterone has been generally regarded as devoid of mammary growth stimulating activity in most species. Its positive action in the mouse appeared to be exceptional[1], though doses of 4 mgm. daily were without effect in the rat[2]. It has lately transpired, however, that massive doses (15 mgm. daily) promote mammary development in the rat[3,4]. Two progesterone derivatives, desoxycorticosterone (21 - hydroxy - progesterone)[5,6], and pregneninolone (anhydro-hydroxy-progesterone)[7] have also recently been shown to exhibit mammogenic activity.

Date	Mothers			Litters			
	Treatment	No. in group	Mean wt. on 6th day of lactation (gm.)	Total No. of pups on 1st day of lactation*	No. of pups weaned	% weaned	Mean wt. at weaning (gm.)
Jan. 1942	Sesame oil (control)	4	303	32	31	97	42·9
,, ,,	10 mgm. progesterone daily ..	4	234	31	29	94	38·4
,, ,,	5 mgm. DOCA daily	4	263	31	30	97	42·3
May 1942	Sesame oil (control)	4	230	32	29	91	40·7
,, ,,	15 mgm. progesterone daily ..	3	250	24	22	92	40·7
,, ,,	10 mgm. DOCA daily	3	237	24	22	92	37·6
,, ,,	4 mgm. pregneninolone daily ..	3	240	22	22	100	35·4

* Litters were reduced to eight at birth.

In 1937, Folley and Kon[8], on the basis of existing evidence, put forward the generalization that substances showing mammogenic activity also possess the power to inhibit established lactation. The question therefore arises whether or not this generalization is in accord with the new facts mentioned above. The effect on lactation in rats of the three steroids in question was accordingly investigated.

The experimental technique and method of studying lactation were as described previously[8,9], facilities for working with rats being kindly provided by Dr. S. K. Kon. Progesterone and desoxycorticosterone acetate (DOCA) were given by subcutaneous injection in sesame oil (1 ml. daily). The administration of large doses of pregneninolone presented some difficulty on account of its relative insolubility. For this reason the maximum daily dose that could be conveniently given was 4 mgm. dissolved in 2 ml. of propylene glycol. In the first series of experiments (January 1942), ten consecutive daily doses were given and in the second series, eleven, in all cases beginning on the sixth day of lactation. The results are summarized in the accompanying table.

It is evident that in the experiments with progesterone and desoxycorticosterone acetate no detectable inhibition of lactation occurred. Folley and Kon[8] had already shown that administration of 1 mgm. progesterone daily to rats had no inhibitory effect on lactation; it is interesting now to find that in rats from the same colony doses fifteen times as great are equally without effect. It may be noted that the dosage per unit of body weight in these experiments is smaller than that which Selye[3] used to obtain mammary growth, since his rats weighed only 108–141 gm., but mammary growth was reported by Reece and Bivins[4] using the same dosage in rats weighing 217 gm.

The negative results with 5 mgm. and 10 mgm. of desoxycorticosterone acetate daily are rather surprising, since Gaunt[10] in experiments on adrenalectomized rats obtained slight evidence that desoxycorticosterone inhibits lactation. However, in intact rats receiving 0·5 mgm. daily, he observed no inhibition.

Only with pregneninolone was there any evidence of interference with lactation. In this group the growth curve of the pups underwent a slight depression beginning immediately after the injections were instituted.

It might appear from these results that the generalization proposed by Folley and Kon is no longer tenable. It is possible, however, that the threshold for the mammary growth response may be lower than for inhibition of lactation and that administration of even higher doses of these steroids might give positive results. These results are published now since they are of some interest and because further experiments with higher doses of progesterone are unlikely to be possible in the near future.

I am indebted to Messrs. Organon Laboratories Ltd. for progesterone and desoxycorticosterone acetate, to Messrs. Ciba, Ltd., for desoxycorticosterone acetate and anhydro-hydroxy-progesterone and to Messrs. Schering, Ltd., for progesterone provided before the War.

Collection of Eggs from the Fallopian Tube of the Rat

DURING the course of recent experiments in collaboration with Mr. P. C. Williams, an account of which will be published later, it has been noted that ovulation and superovulation can be produced in both intact and hypophysectomized immature rats by a single injection of mare serum gonadotrophin followed by a single injection of chorionic (urinary) gonadotrophin. In hypophysectomized rats, ovulation takes place 13–14 hours after the administration of the luteinizing hormone (chorionic gonadotrophin). The number of eggs produced may be very large; in one rat no less than forty-nine eggs were present in the Fallopian tubes.

In keeping with the observations of Long[1], I have examined the Fallopian tubes of such rats in the fresh condition in order to avoid the cutting of a large number of serial sections, and to facilitate the rapid collection of the eggs. The method adopted is as follows: The Fallopian tube is uncoiled by microdissection. When superovulation has occurred, macroscopic observation reveals a characteristic swelling or bulging of a short length of the tube near its ovarian end. This swelling, visible to the naked eye, has a glassy appearance which is in sharp contrast to the opacity of the remainder of the tube. Under a binocular dissecting microscope the swollen part of the tube is seen to contain the eggs (Fig. 1). Each egg is surrounded by a dense mass of cumulus cells, and the cell-masses are held together by a translucent gelatinous fluid (Fig. 2). Ovulation of the normal number of eggs does not produce a cell-mass big enough to cause this swelling, though the binocular microscope enables the eggs to be seen quite easily in the tube, as described by Long. The eggs are collected by excising the egg-containing segment of the tube, and applying gentle pressure at one end of the segment to squeeze out the contents.

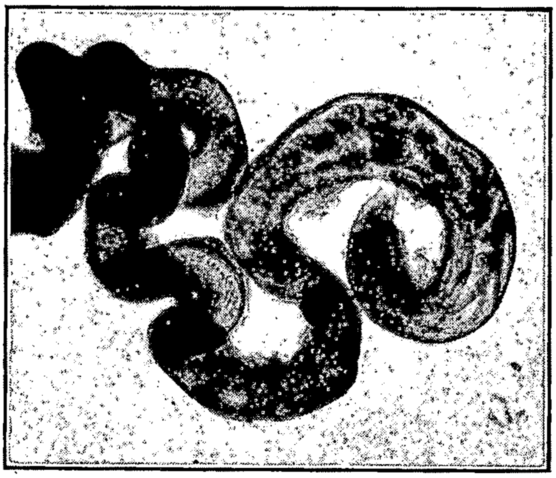

Fig. 1.

FALLOPIAN TUBE OF HYPOPHYSECTOMIZED RAT AFTER SUPEROVULATION, SHOWING THE SWOLLEN EGG-CONTAINING SEGMENT. (×15)

Long removed the surrounding cumulus cell-mass and corona radiata by immersing the eggs in a sperm suspension, but the recovery of the eggs is then made difficult by the opacity of the fluid. I have made use of the observations of Yamane[2] and Pincus and Enzmann[3] that the dispersal of the follicular epithelial cells surrounding the egg can be effected by the supernatant fluid from a centrifuged suspension of spermatozoa previously killed by heat, or by a solution containing trypsin. The former of these methods has been applied with success. A sperm-free solution, prepared in this way, causes disintegration of the cumulus and corona radiata surrounding the egg of the rat in about one hour. The eggs, now surrounded only by the zona pellucida, can then be removed with comparative ease from the medium.

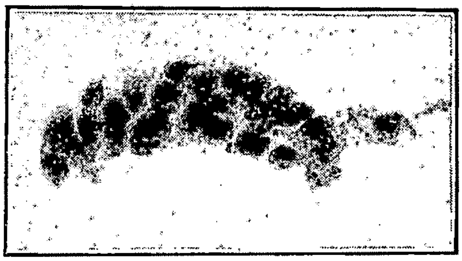

Fig. 2.

CONTENTS OF THE SWOLLEN SEGMENT, ABOUT 20 EGGS SURROUNDED BY CUMULUS CELL-MASSES CAN BE COUNTED. (× 15)

Vitamin C in Walnuts

THE fact that unripe walnuts (*Juglans regia*) contain very large amounts of vitamin C appears to have been first reported by Gergelezhiu[1] in 1937. This remarkable observation that a fruit as large as the walnut contains 1,000–3,000 mgm. of vitamin C per 100 gm. appears to have been overlooked in English-speaking countries although the findings have since been confirmed by German workers[2]. It has been shown by the Russian author that the vitamin C content is at its highest at the stage of development when the kernel is soft and just before the formation of the shell.

TABLE 1

VITAMIN C IN DIFFERENT SPECIES OF WALNUTS

	mgm. per 100 gm.
Juglans regia—source A	1460–1800
—source B	1520–1640
Juglans regia v. *sinensis*	1120
Juglans cathayensis	860
Juglans nigra	700
Juglans cordiformis	680
Juglans rupestris	510
Juglans mandshurica	410

We have recently examined a number of species of walnuts. It can be seen from Table 1 that of these the cultivated edible walnut contained the highest concentration of vitamin C. The figures for the less common Juglans species must be taken as approximate since it was not possible to ensure that the specimens were analysed at the stage of development when the vitamin content was highest.

The analyses shown in Table 1 were carried out on the whole fruit by the usual titration with 2.6 dichlorophenol indophenol. In order to verify the specificity of the method for green walnuts the following tests were done. Although Harris and Olliver[3] have shown that tannins are unlikely to interfere with the vitamin C determination, Gatti and Knallinsky[4] have reported that such substances reduce the dye. Precipitation of walnut extracts with gelatin and acid salt solution, which completely removed the reducing activity from tea extracts, caused no reduction in the apparent vitamin C concentration of the walnuts for 30 minutes. Furthermore, treatment of walnut solutions with ascorbic oxidase prepared from cucumber[5] caused a loss of 98·4 per cent of their activity. The high indophenol-reducing properties of walnuts appear, therefore, to be due to vitamin C.

In order to discover whether this surprising concentration of vitamin C was a characteristic of the walnut or was shared by other nuts a number of different types were examined. All these nuts were in an unripe condition similar to the walnuts.

TABLE 2

VITAMIN C IN UNRIPE NUTS

		mgm. per 100 gm.
Juglans regia	walnut	1460–1800
Pterocarya Rehderiana	Rehder's wingnut ..	1540
Carya ovata v. *pubescens*	a hicory	820
Carya ovalis v. *obcordata*	,, ...	580
Carya glabra	,, ...	460
Pterocarya sternoptera	a wingnut	440
Carya alba	a hicory	70
Æsculus Pavia	a horsechestnut ..	20
Prunus Amygdalus	almond	20
Æsculus Hippocastanum	common horsechestnut	8
Æsculus carnea	red horsechestnut ..	5

In spite of the active enzyme systems in walnuts which cause rapid blackening when cut surfaces are exposed to the air, Gergelezhiu found that the vitamin C is remarkably stable. The methods commonly used in the U.S.S.R. for preparing sweet confections from walnuts, however, destroy all the vitamin C. The pricking and brining, followed by exposure to sunlight or treatment with steam used in making the pickled walnuts popular in Great Britain also completely destroy all the vitamin content. If, however, walnuts are pickled by either of two methods published by Mrs. Hannah Glasse in the eighteenth century the whole of the vitamin C is retained. Walnuts can also be used as a source of vitamin C in the diet in the form of jam or chutney.

TABLE 3

UNRIPE WALNUTS AS A SOURCE OF VITAMIN C IN THE DIET

	Vitamin C mgm. per 100 gm.
1. *Green pickled walnuts.* Unripe nuts peeled very thinly; soaked for 24 hours in 15 per cent salt solution; packed in spiced vinegar (without cloves); left for 3 months	1080
2. *White pickled walnuts.* Unripe nuts peeled until white; soaked for 12 hours in 15 per cent salt solution; transferred to a second salt solution and simmered for 5 minutes; packed in spiced vinegar (without cloves); left for 3 months ..	1070
3. *Walnut marmalade.* 230 gm. unripe nuts sliced into 560 ml. boiling water; boiled until soft (40 min.); 340 gm. sugar added, boiled until set (20 min.)	630
4. *Walnut and blackcurrant jam.* Jam made with 453 gm. nuts, 112 gm. blackcurrants and 560 gm. sugar	520
5. *Walnut and green tomato chutney.* 680 gm. nuts, 453 gm. green tomato, 225 gm. shallots, 225 gm. raisins, 225 gm. sugar, 5 gm. mustard seed, 15 gm. salt, 880 ml. vinegar, 25 ml. saccharine solution ..	410

The samples of pickles, of which the analyses are given above, were made in 1940. The determination of vitamin C was carried out in August 1942. When it is considered that orange juice contains about 45, rose-hip syrup 200 and blackcurrants 300 mgm. vitamin C per 100 gm., the concentration in walnuts pickled as indicated above is very remarkable. A single walnut weighing 15 gm. will provide 150 mgm. of vitamin C, or at least twice the maximum daily requirement.

Mating Swarm in a Chironomid, *Spaniotoma minima*

A DIFFICULTY often encountered in the study of the habits of mosquitoes is the failure of many species to mate in confined spaces in the laboratory. To overcome this difficulty larger and larger chambers have usually been constructed to gain space for the formation of a mating swarm (Hackett[1]). Lloyd[2] notes this difficulty with the chironomid, *Spaniotoma minima*, one of the common sewage flies. In the course of recent investigations I have succeeded in overcoming the inhibition in this species without enlargement of the insectary, and the conditions found to limit the mating of this insect may have possible applications to malariological problems.

The insects, which are positively phototropic, were found to mate very freely in small glass bell-jars, if the light was not decidedly from one side. Screening the window light and placing an electric lamp directly over the bell jar resulted in a typical dance, accompanied by free mating. In a glass box, 20 in. × 10 in. × 12 in., swarming was most active when the source of light was directly above, but swarming and mating also occurred with illumination from below and also, though less freely, when the four sides of the box were equally illuminated. All round, rather than unilateral, illumination would seem to be essential, therefore.

Below 10 foot-candles, swarming in laboratory cages declines with decreasing light intensity. In the field the flies are found swarming in early morning so soon as it is possible to perceive them and before the photometer will register (that is, below 0·25 f.-c.). The swarms increase with increasing light and in calm weather the flies may be seen dancing in great abundance in bright sunlight, so that swarming occurs over a wide range of light intensity. The lower temperature limit for swarming is 46° F. and for mating 48° F. There appears to be no upper limit for either process under natural conditions. Swarming has been seen to take place on hot, dry days in summer and also during fog and rain. Relative humidity therefore seems to have no influence on its occurrence. When temperature is favourable, wind is the most important factor governing the occurrence of swarms in the field. At velocities below 50 ft. a minute swarming is at a maximum and is progressively reduced up to 200 ft.

a min. (2·27 m.p.h.), which is about the inhibiting force. When wind is of interfering velocity, shelter is chosen wherever possible, but, other things being equal, areas of brightest illumination are preferred. Swarms are therefore found (1) over patches of lighter ground colour and reflecting areas (for example, sheets of water), and (2) behind barriers which give shelter or over raised objects which set up eddy currents counteracting the main wind force.

The sexes are equally abundant, but, as is usual with swarming chironomids, males predominate to some 93 per cent in the established swarm. When, however, a swarm is freshly induced in the laboratory, the proportion of females is at first high, but since the males return to the swarm after mating, whereas the females do not, the customary sex proportion (93 per cent males) is soon attained. Single females or single males will dance freely with the same characteristic motions.

Swarming does not appear to condition the reproductive organs of the males for copulation, and no change is found in the distribution of sperm after dancing. The purpose of the swarm appears to be to bring the sexes of a species together, since the various species of swarming Diptera form dances characteristic in height and pattern, and probably also to stimulate the insects to the necessary pitch of excitement for successful copulation.

Cambridge Scientific Workers and the War

IN an article under the above heading[1], the following passage occurs in reference to research topics suggested or approved by the Advisory Research Council of the Chemical Society: "It was stated that the majority of these problems are long-term problems related to the improvement of the post-war prospects of the chemical industry. . . ."

No such statement has been made, by me as chairman of the A.R.C.C.S., or in any authorized pronouncement of this body. The topics adopted cover a very wide range and many are directly related to the war effort or to conditions arising from the War; a considerable number have a chemotherapeutic or medical interest. In a number of cases the investigator has been put into direct touch with a Government department and an extra-mural research of that department has been started as a result. On the other hand, it is true that we have accepted suggestions made by the chemical industry, and we have done this in the belief that stagnation must result unless development is continuous.

The organic chemical industry, like the human body, has certain permanent elements, but it also includes much that needs rejuvenation and constant improvement. It must be emphasized that all the work of this kind, sponsored by the Council, has been suggested by industry itself; we have initiated none of it.

It is true that studies of industrial interest have been made, with great success, at Cambridge, and an explanation on the above lines has probably been given. But it is an argument from the particular to the general to conclude that all, or most of, the work recommended by the A.R.C.C.S. is of this character.

Just as Mr. Churchill declared that the popular demand for a second front was a healthy sign, so we must all sympathize with the agitation for the better use of scientific workers in the War without necessarily agreeing that all the panaceas put forward are feasible. The subject bristles with difficulties and it is often forgotten that a considerable scientific man-power is already available to the Ministries in their research establishments and existing extra-mural contacts with university and industrial laboratories. Obviously it is only a residuum of worth-while *ad hoc* problems that cannot be tackled. During a war we have to find men for jobs, not jobs for men.

It is equally clear that the directors of official research and their assistants and consultants have no monopoly of originality, initiative, foresight, or knowledge; no one of them would claim that he must have thought of everything. Therefore, the pressing need is not for the farming out of specific tasks but rather for the elaboration of a mechanism of contact so that fresh minds and new ideas may be brought to bear on our problems.

Failing such opportunities for present service, need anyone be ashamed of pursuing what is strangely called 'academic' research? Students must be trained in technical subjects and consequently must have teachers. If the latter can find war work to do in addition, it is all to the good; if not, they are still useful and necessary members of the community and it is their duty to keep themselves intellectually alive by making contributions to knowledge. Experience shows that the enthusiasm of undergraduates is fully evoked only by direct contact with teachers inspired by the spirit of active investigation.

A speaker at the conference, of which the article referred to is a summary, defined 'war research' as work which will *very probably* give results applicable to *this* war. Earlier it is stated that junior members of university laboratories should be provided with more of the right sort of problems to solve. The combination of these views implies a serious criticism of the scientific activities of the Ministries which would be hard to justify. Is it suggested that there exists a mass of clearly useful short-term projects which has been neglected? If it is so, the remedy should be the strengthening of the official technical establishments (possibly extra-murally) because, once a short-term desideratum has been recognized, it must be attacked energetically and cannot be left to unconnected volunteers. Therefore we must envisage an expansion of extra-mural contracts with the universities, and teachers outside these arrangements should make independent efforts to get inside them. Failing this, real research by teachers is real national service.

[1] NATURE, 150, 186 (1942).

WE are glad to publish Sir Robert Robinson's communication since, as he points out, individual men of science and, indeed, scientific bodies, in their enthusiasm, seem to forget that much is already being done both within and outside the various Ministries. We feel, however, that during a war we should find not only men for jobs but also jobs for men. The Central Register is now extending its activities to cover the latter.—EDITORS.

NATIVE PROTEINS, FLEXIBLE FRAMEWORKS AND CYTOPLASMIC ORGANIZATION

By Dr. DOROTHY WRINCH
Amherst, Smith and Mount Holyoke Colleges, Mass.

A REVIEW of recent work in physical, physiological and enzyme chemistry, and crystallography[1] yields a rather definite and precise picture of the native protein. In consequence of the widespread phenomenon of the reversible dissociation of native proteins into aliquot parts[2], it is necessary to assume that the native proteins, consisting in some cases of molecules in monomeric form—which we shall call protein units to indicate that they cannot dissociate further without losing their protein character—are in many cases particles, consisting of aggregates of protein units[3]. The protein unit, it appears, is a rigid atomic framework formed by the interbonding of the skeletal atoms of the residues. In consequence the C_α atoms carrying the amino acid *R*-groups and the C_α—N atoms holding the imino acid rings form fixed patterns in space. It is, we suggest, the spatial patterns of the N—C_α—C atoms in the skeletons which define the protein character and the allocations of this and that variety of residues to the various positions in these skeletons which define the specific characters of individual units. Such a picture, suggested by data from so many fields, seems definitely required by immuno-chemical findings[4], which make it necessary to postulate that the specific *R*-groups on protein antibodies are held in spatial patterns on the molecular surfaces[5]. To complete the description of protein particles and protein frameworks in general, it is necessary, in addition, to specify the way in which the individual protein units—which need not be identical—are associated. It is the nature of these associations and the implications regarding the nature of systems of native protein units in general which are the subject of this communication.

It seems probable, as has often been suggested by protein chemists, that the units are in some cases held together by means of covalent bonds, for example, when a cystine residue is knitted into the skeleton of two units or when peptide bonds are formed between basic and acidic *R*-groups of different units. Evidence as to the mild treatments which disrupt some protein particles indicate, however, that in many cases the association is not of this type, and a study of structure analyses of crystals of molecules containing groupings of the types present in the *R*-groups of proteins provides a number of precise suggestions as to possible ways in which associations can occur. We find two different kinds: by means of polar links and by the apposition of comparatively non-polar groups[6].

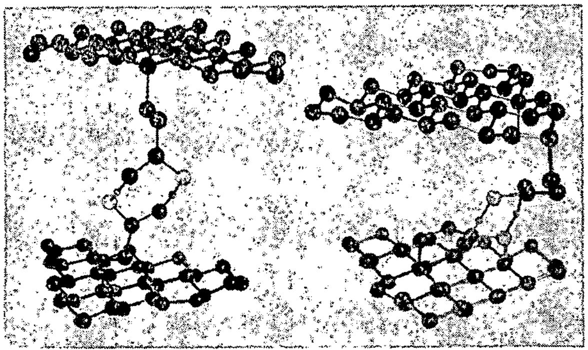

Fig. 1.

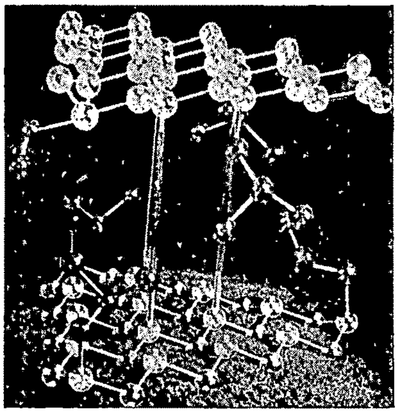

Fig. 2.

The first set includes the following, each based upon a precedent established by structure analyses. (I) Association by hydrogen bridges of glutamic or aspartic acid *R*-groups through their carboxyl groups, with or without the intermediary of 'foreign' molecules (for example, waters). (Precedents: formic acid, oxalic acid and oxalic acid dihydrate.) (II) Association by hydrogen bridges of residues the *R*-groups of which contain COO^- and NH_3^+ groups. (Precedents: glycine, alanine.) (III) Association of *R*-groups containing hydroxyls, with or without metallic ions as intermediates. (Precedents: sugars and metallic hydroxides.) On the basis of the distribution of oxygen atoms around metallic ions in the latter cases, similar associations of COO^- groups on glutamic or aspartic acid residues may also be suggested. (IV) Association by hydrogen bridges of acid amide residues through their CO—NH_2 groups, as shown in Fig. 1, in which the apposed portions of skeletons are indicated diagrammatically by laminæ of atoms. (Precedent: acetamide.)

Suggestions regarding the second type of association, depending upon van der Waals attractions between less polar groups, can be obtained from a study of hydrocarbon crystals. As an example, Fig. 2 shows a possible (trigonal) arrangement of leucine residues on apposed faces, terminal methyl groups from each surface fitting into pockets formed by terminal methyl groups on the other.

The considerable surface areas on native proteins can thus be held together, provided enough groupings are associated. An array of trigonally arranged glutamine residues, for example, on each of two apposed surfaces, could interlink somewhat as in the acetamide crystal. This and the leucine case provide examples of the way in which *R*-groups, *when rooted in an atomic fabric*, can form surfaces of high specificity and how such patterned surfaces can complement one another, as occur in immunological phenomena[5].

The association of homologous chromosomes may prove capable of interpretation in terms of such patterns, in the special case in which they are not only complementary but also self-complementary. Such interrelations between surfaces, permitting the simultaneous associations of groups each no stronger than those holding together molecules of normal size, but all together adding up to a considerable sum, would seem to be one of the essential factors in the crystallization of megamolecules, as well as in the formation of megamolecular particles[7], including antigen-antibody complexes[5].

Both types of association may also be expected to take place intramolecularly, thereby stabilizing the native protein structure. That such associations (for example, of acid amide groupings) may be a major factor in stability is indicated by recent studies[8]. When they take place intermolecularly, the various orientations and degree of extendedness of the *R*-groups (see Fig. 1) give a certain flexibility to the particle. Just as a molecule consists of atomic units held together by covalent bonds, so a protein particle consists of protein units held together by the association of skeletal atoms and/or *R*-groups, but whereas the strongly bonded atoms hold each other at definite distances in definite directions, the native protein units associated through their polar or non-polar groupings do not. Such associations allow them to lie at various distances apart up to a fixed maximum and in a variety of orientations. I suggest that this aspect of the possible types of associations of native protein units gives the key to the 'plasmolytic' capacity of many native proteins to form crystals containing very different water complements[9]. They also suggest an explanation of the nature of cytoplasmic organization and of the many 'anomalous' properties of protoplasm.

It should also be pointed out that this idea of cytoplasmic organization as depending upon flexible frameworks of native protein molecules leads at once to a simple hypothesis as to the nature of biologically active membranes. On this picture they are to be regarded as *molecular fabrics*, that is, as two-dimensional arrays of native protein units, interlinked by *R*-groups, possibly with some ions[10] and other foreign molecules (water, sugars, lipids, etc.) as intermediates: possibly as two or more of such fabrics superposed. Points at which the native protein units are interlinked by groupings of non-polar character will then be permeable, highly selectively, to non-polar molecules. The open structures in the neighbourhood of interlinking *R*-groups of polar type, the stereochemical requirements of which prevent a closely packed arrangement, will permit the passage of water molecules and of polar molecules of suitable size, shape and nature. In particular, the type of association suggested in (III), following the study of the possible intermolecular links in the insulin crystal, would seem to throw light on some of the striking facts regarding the effect of, for example, copper in very low concentrations on biological membranes[10].

Detailed suggestions as to the nature of these various types of flexible frameworks which appear to form an essential feature of living systems, including the biologically active membranes and immune bodies, will be published shortly.

THE BRITISH RHEOLOGISTS' CLUB

THE seventh general meeting of the Club was held at the laboratories of the Electrical Research Association, Perivale, Middlesex, on July 25, Dr. Stanley Whitehead being in the chair.

A discussion on the "Design and Standardisation of Rheological Apparatus" was introduced by Mr. J. G. Gage. Mr. Gage quoted Bingham's remark that the apparatus used in the young science of rheology corresponded to that used by Faraday in the early days of electrical science. He went on to outline the four main types of flow-curve with which rheologists are familiar, corresponding to Newtonian, pseudo-viscous, plastic (Bingham) and hysteresis systems, in the last of which the flow-curve depends on stress history. He briefly described the principal types of instrument used to study these systems: capillary viscometers, which he regarded as unsatisfactory for thixotropic systems; Couette and Stormer rotation instruments; the multiple jet Gardner mobilometer and its modifications; falling sphere viscometers, etc.

Mr. de Waele disagreed with Mr. Gage's views on the relative merits of capillary and rotation viscometers, claiming that we know more of the hydrodynamics of the capillary tube than of the rotation instrument. He regretted that the work of Rabinowitsch had not been more widely appreciated. In his experience all materials give linear flow-curves if high enough stresses are used and he was sceptical about the existence of sharply defined yield-values.

Commander Goodeve, in discussing thixotropic systems, pointed out that the properties of materials are changed by shearing them, and flow-curves for fully broken-down and completely rested materials cannot be obtained. He explained his "coefficient of thixotropy" and discussed its relation to mobility and yield-value. Dr. Scott Blair stressed the difficulty experienced by rheologists engaged in war-work in getting experimental instruments made when required in small numbers. The intermediate stage between the home-made apparatus and the catalogued standard article was most difficult to bridge. He appealed to instrument makers for help in this matter. Mr. Thomas discussed the rheology of plastic insulating materials and criticized the use of the Martens' test, which he regarded as unsound. Mr. Tayar asked whether the use of an eccentric inner cup in a rotation instrument to prevent "channelling" or slipping was sound in principle.

Dr. White considered that there were many instrument giving useful practical results which were not above reproach on theoretical grounds and that the instrument referred to might be little or no worse than many others. He suggested that the use of integral equations might be of great benefit to rheology. Mr. Plesch stressed the importance of differentiating the degrees of accuracy needed for different instruments. Rheological apparatus used in industry differed widely in this respect. Dr. Wearmouth discussed the rheology of plastics studied over a wide range of temperature, about 200° C. At some temperatures some of these materials showed well-marked yield-values, whereas at others, and often over a wide temperature range, there were no yield-values or the yield-values behaved in a quite erratic manner. The industry wanted a single instrument, if possible, to cover the whole field of behaviour.

Dr. Whitehead, in closing the discussion, pointed out the analogy with the problem of dielectrics and discussed the Hopkinson superimposition principle. He also supported Dr. White's stressing of the importance of integral equations. He mentioned the importance of considering the energy aspects of rheological phenomena and added that he felt that British rheologists were at a disadvantage as a result of the lack of adequate journals for applied physics in Great Britain.

PROTECTIVE MULTIPLE EARTHING

IN 1941 the Council of the Institution of Electrical Engineers set up a special committee to consider the problems arising from the increasing use of multiple earthing of the neutral conductor in factories and other buildings, and the report of the committee has now been published (*J. Inst. Elec. Eng.*, 89, Pt. 1, No. 19; July, 1942). The report describes briefly the earthing protective methods generally employed in urban and rural areas and in cities, their advantages and disadvantages. Where underground cables are used, the sheathing and armouring of the cables are employed as the earth return path; alternatively, where available, continuous water mains with metal-to-metal joints may serve the purpose. Where neither of these is available, a separate earth electrode can be used at the consumer's premises although often the cost of an efficient earth is disproportionate to that of the electrical installation itself. Another method utilizes the supply company's low-voltage insulated neutral conductor, connexion being made thereto of each consumer's earth-continuity conductor.

Protective multiple earthing consists of the last-mentioned method, with the addition of multiple connexions of the neutral conductor to earth at other positions on the low-voltage network, and of a connexion between the neutral conductor and earth at each consumer's premises; the earth continuity wire may be dispensed with but this is not recommended. Finally, miniature circuit breakers responsive to very small leakage currents are used.

The Committee's recommendations are as follows: (1) In areas where the supply authority's distribution network consists of underground cables, there should not be any relaxation, other than that contained in Regulation 4, of the Electricity Supply Regulations (1937), which requires earthing at one point only. (2) In areas where the supply authority's overhead distribution system is at low or medium voltage, and where it can be ensured that the distribution network and the consumers' installations are under the same control, so far as the earthing arrangements are concerned, protective multiple earthing would provide a satisfactory alternative to existing methods, and might be permitted. (3) Where the supply is separate from the supply authority's distribution network (that is, where a double-wound transformer or private generating plant is used), a multiple-earthed neutral conductor might be permitted subject to specific conditions being imposed to provide against the risk of interference and possible damage to telephone circuits and apparatus, of gas pipes normally carrying current, of water pipes carrying anything but short-duration fault currents, and of light lead sheaths of telephone cables carrying power currents; these and other contingencies are outlined in an appendix.

Three appendixes are given: (*a*) use of a multiple-earthed neutral conductor where the supply is separate from the supply authority's distribution network; (*b*) protective devices responsive to very small leakage currents and actuating circuit breakers on the consumer's premises; and (*c*) definition of "connected with earth".

The report was submitted to the Electricity Commissioners, who expressed the following views. When protective multiple earthing is adopted, all consumers' installations should comply with conditions as to earthing on the lines of those recommended in Technical Report *F/T* No. 122 (1940) of the British Electrical and Allied Industries Research Association; in the case of consumers' installations existing at the date of adoption of such earthing, the responsibility for the installation complying with the conditions should rest upon the electricity undertakers. It would appear that the Wiring Regulations (Nucleus) Committee takes the view that there should be a continuing responsibility on the undertakers in respect of the condition of the consumer's installation, and if this be the case, the Commissioners in making regulations concerning protective multiple earthing will consider carefully to what extent they could properly impose such responsibility on the undertakers. The Commissioners are of the opinion that it is better, in view of the possible danger which the Committee has pointed out, that the earth connexion on live circuits should not be broken, and that no variation in practice in this respect should be made depending on the voltage of the circuit. They have decided, therefore, to make an appropriate amendment of Regulation 4 (iv) of the Electricity Supply Regulations (1937) on the lines of that suggested by the Committee, when a suitable opportunity occurs. When, on the grounds of cost or convenience, a link is not included in the earth connexion, the use of a suitably designed 'clip-on' ammeter should enable leakage tests to be carried out on live circuits without interrupting the connexion with earth.

FORTHCOMING EVENTS

Friday, September 4

ASSOCIATION OF SCIENTIFIC WORKERS (at Caxton Hall, Westminster, London, S.W.1), at 7 p.m.—Open meeting to discuss and support proposals for a Central Scientific and Technical Board. (The speakers will include Lord Strabolgi.)

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

UNIVERSITY CHAIR OF CHEMISTRY, tenable at the Royal Cancer Hospital—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (September 1).

JUNIOR EDUCATIONAL PSYCHOLOGIST at the Child Guidance Centre of the Nottingham Education Committee—The Senior Medical Officer, 28 Chaucer Street, Nottingham (September 2).

ASSISTANT LECTURER IN MECHANICAL ENGINEERING—The Registrar, College of Technology, Manchester 1 (September 7).

REGIUS PROFESSOR OF ENGINEERING at Edinburgh University—The Private Secretary, Scottish Office, Fieldon House, 10 Great College Street, London, S.W.1 (September 7).

HEAD OF THE CHEMISTRY DEPARTMENT—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (September 12).

HARRIS CHAIR OF PHYSICS, University College, Dundee—The Secretary, The University, St. Andrews (December 31).

LECTURERS AND INSTRUCTORS FOR TRAINING RADIO MECHANICS—The Principal, College of Technology and Arts, Eastlands, Rugby.

TEACHER FOR DAY AND EVENING ENGINEERING CLASSES—The Principal, County Technical College, Gainsborough, Lincs.

PRESERVATION OF OXFORD

WHILE it is recognized that without some measure of central direction and regional guidance there can be no re-planning and reconstruction of our towns or countryside which will ensure the best use of the nation's reserves of land, the right balance between industry and agriculture, between work and leisure, that is, the best from the point of view of social and cultural as well as material needs, it is in the application of the planning principles and policy to particular local problems that the individual citizen is most interested. Those are the consequences that are likely to provoke his most speedy reaction, and his support of, or opposition to, any Ministry of Planning. He will judge of its value by the results that he can see in the district most familiar to him.

On that ground the report of the Committee on Planning and Reconstruction appointed in November 1940 by the Oxford Preservation Trust is indeed of more than local interest. The second part of the report which has now been issued (see page 297) deals with questions directly related to the old University City of Oxford, and includes a summary of the conclusions presented in April 1941 in the first part of the report, which was concerned with planning for the Oxford region and how far the measures that are necessary locally are dependent on national action. But the national interest of the second part of the report is actually scarcely less than that of the first part, in spite of its narrow scope, and the announcement of the endowment of a chair of social medicine at Oxford by the Nuffield Trust gives a sufficient clue to the fundamental reason.

The report gives a good historical sketch of the changes in Oxford in the last generation and of the acute problems which continued development presents. The evils described still remain and may be greatly intensified in the future. Indeed, the unique character of the Universities of Oxford and Cambridge is something worth cherishing and worth defending as a national rather than as a local inheritance only. It would be a national disaster and no mere local tragedy if we allowed rapid and uncontrolled industrial development to thwart either the growth of the university in such directions as Nuffield College has stimulated or the remoulding of the City of Oxford itself and its preservation from the sordid encroachments that have been allowed to sully it.

No city, in fact, has a greater duty and a greater opportunity than Oxford to take a leading part in the movement to remould social conditions and to add fresh splendours of architecture, new beauties of park and garden and spacious emplacement to our heritage. The study that has already been given to the physical planning of town and country has eased the way, and the times are favourable, not only for taking further preventive measures to safeguard the University and City from further detriment, but also to remedy, so far as practicable, the injuries already suffered, as well as to adopt a broad constructive policy for the future. The report outlines a complete scheme for the preservation and ordered development of Oxford, undeterred by doubts as to its financial feasibility. It recognizes the need for careful consideration of existing interests—that a city is not a mere collection of buildings with services of roads, light, water and the rest. With its emphasis on the community and its individual and social needs, it advances a plan bold and comprehensive enough to command wide approval.

The report points out that it is almost impossible to forecast what may be the extent and nature of future developments in the University, and it is of the utmost importance therefore that a generous view should be taken of the need there may be for expansion on the part of the University and the colleges. Through lack of foresight and collaboration, they have made not a few mistakes in the past, and the University can already provide examples of the consequences of defective planning. Moreover, the tendency noted in recent years for research institutes to seek establishment in Oxford may develop very greatly after the War; and should the number of university students even equal that at Cambridge, much fresh building would be required for their accommodation. It is doubtful whether it has been sufficiently considered how many new sites of liberal extent may be required if, after the War, Oxford were to prove, as it well might, a far more powerful magnet for the attraction of specialists and students from all over the world than it has in the past.

The splendid new facilities for bringing research into contact with the problems of medicine and of social and economic organization made possible by Lord Nuffield's benefactions are a pointer in this direction which should not be overlooked any more than their implications for civic development. The University of Oxford is no longer an institution catering for only one section of the nation. At least half its students are drawn from the less wealthy classes of the community. Its teaching and research embrace the social sciences, and members of the University have proved themselves as leaders in many departments of the national life. Moreover, just as the welfare and environment of the University is not a matter of merely local concern, so the embellishment of the City of Oxford with a civic centre and other developments recommended in the report to rescue it from its present disfigurements, and with the new features that are proposed, and adequate hotel accommodation, should lead to an even greater number of visitors to Oxford, with much financial benefit to the catering and other trades of the city. Its proximity to Stratford-on-Avon would help to make the district one of the principal centres for visitors from the Continent, the Dominions and Colonies and the United States.

In regard to industry, the report concludes that the industries now established should not be subjected to any harassing restrictions, but every effort should be made to serve their welfare. On account of the historic character of Oxford, any tendency to develop it into a great industrial city is to be deprecated and should be forestalled. No heavy industries should be permitted to establish themselves and no sporadic industrial expansion should be allowed. Certain facilities should be given for the establishment of additional light industries, and any proposal that might be made for creating an industrial estate for this purpose should be considered sympathetically. The most valuable location for such an estate would be in the neighbourhood of Cowley, on land already zoned for industry in the Mid-Oxfordshire Planning Scheme.

According to the report, there are strong reasons for an entirely new departure in connexion with a civic centre. Such a centre should be designed so as to meet all the requirements of a modern municipality, and the error of cramping the site and leaving no room for future developments, committed by so many of our towns, should not be repeated here. Again, in regard to housing, the report stresses the importance of making sufficient provision for social needs in planning all new housing estates.

The committee has wisely included as an annexe to its report a report of the Oxford City Council's proceedings on the plan for redevelopment, which indicates the measure in which the Oxford Preservation Trust's proposals are likely to find local support. What emerges from this report is, in fact, the extent to which local opinion is ahead rather than behind Government action, and the general impatience at the slow progress under the Ministry of Works and Planning. This is notably true of several of the badly damaged towns which, following the example of Coventry, have been quick to realize the opportunities now to their hand for redressing past mistakes and errors.

The procedure suggested in the report is that the Oxford City Council—in conjunction with the two neighbouring County Councils, if they concur—might approach Parliament with a view to the passage of a special Act, for the establishment of a statutory commission to carry out such improvement scheme as might be adopted. The City Council should have the right to nominate a majority of the members of such a commission, on which both the County Councils of Oxfordshire and Berkshire as well as the University would be duly represented. The commission would have executive powers to carry out schemes in co-operation with the local authority concerned. Such a plan would avoid difficulties and delays which would otherwise occur from existing local boundaries, and would enable new financial sources to be tapped while protecting local interests. Any special powers for the acquisition of land could be embodied in the Act.

The broad outlines sketched above of the scheme for the re-planning of Oxford and its environs put forward by the Oxford Preservation Trust will serve to indicate the active interest which is being shown in the future utilization of the countryside of Great Britain. It is typical of many local efforts, which when integrated should make of the country a better place—a place in which both cultural and material needs are duly considered. The Ministry of Works and Planning must see that this local interest is fostered and, where necessary, guided to serve the needs of the country as a whole.

GOETHE'S SCIENCE

Goethe on Nature and on Science

By Sir Charles Sherrington. (The Philip Maurice Deneke Lecture, delivered at Lady Margaret Hall, Oxford, on the 4th March, 1942.) Pp. 32. (Cambridge: At the University Press, 1942.) 1*s*. 6*d*. net.

GOETHE is the only considerable poet who devoted much of his time to science and who took himself seriously as a man of science. Make no mistake, he took himself very seriously: he said, for example, to Eckermann, "I do not attach importance to my work as a poet, but I do claim to be alone in my time in apprehending the true nature of colour". Although he might on consideration have tended to revise this estimate of his poetry, it is abundantly clear from other records that he was convinced of the lasting importance of his writings on colour. Shelley took at one time a close interest in chemical experiments; Beddoes, a lesser, but not inconsiderable poet, spent most of his time in anatomical study, but neither of them thought that he had made a substantial contribution to science. Goethe stands alone.

Goethe invented the term 'morphology' and left sufficient mark in this study for him to be quoted more than once in D'Arcy Thompson's great work, "Growth and Form", in particular his aphorism "Das lebendige ist zwar in Elemente zerlegt, aber man kann es aus diesen nicht wieder zusammenstellen und beleben". His wide view of Nature as a living whole led him to make certain shrewd generalizations in the biological field which, while they have failed to win support, still retain an interest, but even in biology the one concrete discovery generally attributed to him, namely that of the intermaxillary bone in the human skull, was not new, having, as is pointed out in the study before us, been anticipated by Vicq-d'Azyr. It was to his investigations and speculations in colour, however, that he was particularly attached, and here his misunderstandings were so fundamental that the "Farbenlehre" has long been a puzzle to physicists, who have been unable to find a consistent or remotely reasonable point of view in it.

Goethe took as his fundamental phenomena those exhibited by light in passing through turbid media, such as colloidal suspensions; for example, that produced by adding a few drops of spirit varnish to water. Unfortunately, scattering phenomena are singularly ill-suited to serve as a starting-point for investigations or speculations on the fundamental physical properties of light and colour. No doubt Goethe was led to give them the foremost place in his teaching because colours due to scattering are particularly common in outdoor Nature, as exemplified by the red sun seen through fog or mist, the colour of distant hills and various phenomena in water containing suspended particles. It is also possibe that he may have been stimulated by de la Hire, who, about a hundred years earlier, put forward views rather similar to his own.

Goethe was an acute observer, and his descriptions of the colours due to scattering are numerous and precise. He attached, however, great importance to the background in observing the blue colour due to light scattered sideways, insisting that it should be black, since black played a great part in his theory. Although, of course, a black background makes observation easier, it is of no fundamental significance. This question of background is exemplified, for example, when, in explaining the colour of the sky, he says, "If the darkness of infinite space is seen through atmospheric vapours illuminated by daylight, the blue colour appears", which is, in a way, an anticipation of the true explanation of the colour of the sky, afterwards given by Rayleigh.* Goethe did understand that the blue of the sky was analogous to the blue of a beam of light in a colloidal solution.

How Goethe endeavoured to wring an explanation of all colours, including those of the prismatic spectrum, from the colours exhibited by scattering media is a long and complicated story of uncritical effort and obstinate misunderstanding. Whenever he was describing what he saw, however, he was clear and accurate, as in his talk of after-images and of simultaneous and successive contrasts. Physicists have been rather unjust to his descriptions of scattering phenomena, which were not properly understood before Rayleigh's fundamental work, and so certainly not by Goethe's early critics. He alienated men of science by his senseless and absurd attacks on Newton, whose point of view—that is, the modern scientific point of view—he was utterly unable to comprehend. He objected to mathematics as something that concealed the truths of Nature, and his ignorance and distrust of the quantitative often led him astray. In one experiment of his, for example, he objected that the red and the blue were not separated, which on Newton's theory they should be. Certainly they should, but a simple calculation shows that the angle between the red and blue ray should be only about a minute of arc, which he could not observe.

Goethe's antipathy to Newton's teaching led him to most ridiculous lengths: he not only accused Newton of deliberately misleading his readers, of "advocates' dodges" and "conjuring tricks", but even called him "a Cossack Hetman"—surely the most inappropriate term of abuse ever used. The very things on which Newton laid emphasis, precise quantitative experiment under carefully controlled conditions, were obnoxious to Goethe, who wanted to observe colours as they occurred in Nature. Newton probably seemed to him something like a Shakespeare critic who should try to explain the beauty and greatness of the poet's work by counting the frequency of occurrence of certain words, or investigating derivations. One does not find the essence of poetry by mathematics.

We are confronted with the question as to how a man of such mental power, vision and industry as Goethe could devote so much time to the problems of science without leaving any mark in the history of science, without being more, so far as his work on colour is concerned, than a psychological curiosity. Towards a solution of this question, which has been much discussed, especially by German writers, Sherrington's slender booklet contributes more than many ponderous works have done. The author is, of course, peculiarly fitted for his task. Not only is he one of the very greatest scientific figures of modern times, but also he is a poet of extreme sensitiveness, grace and perception, a man of profound knowledge and wide sympathies, a scholar, a linguist and, above all, a man of deep human understanding. What has he to tell us?

---

*"M. de la Hire says that the air, which is made white by the rays of the sun, appears blue on account of the black ground of the unenlightened space beyond it". Priestley, "History of Optics", 1772.

He points out that Goethe was a man with a very peculiar and personal view of Nature (not nature) and a man for whom sight was the predominant sense. He thought that Nature was not to be understood by the analysis of the laboratory and the mathematician's desk, but only by concentrating attention on certain *Ur-phänomena*, or bed-rock phenomena—sometimes Goethe speaks of *Grund-phänomena*—which were of especial significance and were open to direct observation. In colour the scattering phenomena (not, of course, so called by Goethe) were fundamental: we always see through media, more or less cloudy, and so the colours which cloudy media produce are of basic importance. In botany he attached great value to the conception of an ideal leaf which his highly personalized Nature always kept in mind. In the animal world she always had an ideal type before her: an advantageous departure from the type in one direction had to be counterbalanced by a disadvantage in some other direction. For Goethe, to attempt to understand Nature was to attempt to understand a personality, a divine personality if you will, but one taking an almost human delight in creation and device. In Sherrington's words: "For him, surely, the Nature he turned to, and addressed so often, was no impersonal principle, no causal concatenation of material forces. Rather, it was a numinous presence, immanent in Earth and Sky, operating the gates of birth and death."

This short thesis, every sentence of which is significant, really does lend a new meaning to Goethe's scientific work and shows it to be the product of a point of view which is consistent, even if utterly removed from that of modern science, as created by Newton. Goethe's labours in science have borne little fruit, but knowledge of them throws a strong light on the character and mode of thought of one who is undoubtedly among the few great writers of all time. The booklet which is now before us not only helps us to understand Goethe but also, which is just as important, to understand Sherrington. It will bring delight to all his admirers, that is to say, to all who know him or know anything of his work, for it shows the master still writing with all the clear imagery and vivid analysis, with all the generous emotion and keenness of perception which have at all times mitigated the severity of his scientific thought.

E. N. DA C. ANDRADE.

PROGRESS IN PHYSIOLOGY

Annual Review of Physiology

James Murray Luck, Editor; Victor E. Hall, Associate Editor. Vol. 4. (Published by the American Physiological Society and Annual Reviews, Inc.) Pp. viii+709. (Stanford University P.O., Calif.: Annual Reviews, Inc., 1942.) 5 dollars.

DESPITE the "ever-narrowing confines of the world in which we can enjoy the friendly intimacies of intellectual collaboration", to which the editors allude in their preface, the present volume is larger than most of its predecessors. One notes that the contents, always predominantly dealing with American work, are now almost entirely American except for references to a few pre-war papers. There is no ground for surprise in this; the numbers of investigators engaged in physiological research is far greater in the United States than elsewhere, at any time, and during the past three years one European country after another has closed down publication. Some of the contributors are more aware than others of work published outside the United States, while some appear to be quite unaware of non-American work; in any event it is unquestionably far outweighed by the large bulk of American work.

The volume contains references to nearly four thousand original papers, and to about the same number of authors' names: the task of selecting these from the enormous bulk of contemporary literature must have been enormous and thankless, though, of course, there is great variability in the available numbers of papers relating to the different reviews. The largest number no doubt are those papers that refer to the physiology of reproduction, and this review, by F. L. Hisaw and E. B. Astwood lists 486 references: in a relatively restricted field such as in the review on the physiological effects of neutron rays, by P. C. Aebersold and J. H. Lawrence, only thirty-one references are given. It is probable that reviews covering more restricted fields, such as that one, are able to quote a larger fraction of the published work than are the ones dealing with richer bibliographical resources. Further, the treatment in such reviews has the opportunity to cover its ground in a more leisurely and thorough manner, and so to be more generally instructive than that of the harrassed and overcrowded branches of the subject.

It would be difficult to pick out any of the reviews for detailed comment, since each is itself a condensation of so much. But one of them did impress the present writer by its originality, and by its suggestion of a new method of approach to physiological problems. This was the article on physiological psychology by Curt P. Richter. It deals with total self-regulatory functions in their relationship to Claude Bernard's concept of the maintenance of a constant internal environment. This constancy is attained not merely by partial physiological responses, but also by behaviour or total organism responses. For example, adrenalectomized rats will, if able, consume enough salt to keep themselves free of symptoms of adrenal insufficiency; diabetic rats took fat and rejected carbohydrate, and so on. After section of the taste nerves, adrenalectomized rats failed to distinguish between water and salt solutions. This behaviour drive opens up a method for the determination of metabolic needs, on the basis of "a little of what you fancy does you good", and instances of markedly unusual behaviour observed clinically may be considered as an expression of the drive to maintain a constant internal environment.

Another useful article is one on applied physiology, by Lieut.-Commander A. R. Behnke, U.S.N., and Captain C. S. Stephenson, U.S.N. This deals largely with various services problems, such as those connected with aviation, diving, submarines, etc. It is realized in the United States that "A prime need in the military service is the application of physiologic knowledge to field practice", and it is also acknowledged that in Germany this is realized to the full. In Germany, for the past five years, some twenty Government-supported laboratories were equipped with low-pressure apparatus for research in military flying, whereas for the same period the United States had only one physiological laboratory engaged in such work. This is a hint that might well be taken in Great Britain, in which the value of physiology is little recognized, perhaps on account of political repercussions connected with the question of experiments on animals.

A mere list of the remaining articles must suffice, able and authoritative though these be. They are permeability, by L. R. Blinks; physiological aspects of genetics, by H. H. Strandskov; developmental physiology, by H. L. Hamilton and B. H. Willier; water metabolism, by J. P. Peters; growth, by G. S. Avery; energy metabolism, by W. H. Chambers, E. Shorr and S. B. Barker; the physiology of the skin, by P. C. Baird, jun., W. F. Lever, and T. D. Spies; the peripheral circulation, by A. P. Hertzman; heart, by M. B. Visscher; blood, by H. P. Smith; the digestive system, by E. J. Van Liere; kidney, by J. A. Shannon; electrophysiology, by R. W. Gerard; the spinal cord and reflex action, by T. C. Ruch; the central nervous system, by M. Hines; the autonomic nervous system, by K. Hare and J. C. Hinsey; sense organs, by H. K. Hartline; metabolic functions of the endocrine glands, by C. N. H. Long; and the pharmacology of drug addiction, by M. I. Smith.

The index is good and extensive, and the type and paper pleasing.

It would be a good feature in future editions if a bibliography of published books and monographs on physiology and cognate subjects for the year could be included as a special appendix. This would be of especial value at the present time, when so many are cut off from sources of information as to new publications.

C. LOVATT EVANS.

CELL RESPIRATION

A Symposium on Respiratory Enzymes

Contributors: Otto Meyerhof, Eric G. Ball, Fritz Lipmann, Kurt G. Stern, Fritz Schlenk, T. R. Hogness, Elmer Stotz, Carl F. Cori, E. A. Evans, Jr., Philip P. Cohen, K. A. C. Elliott, Dean Burk, C. J. Kensler, Erwin Haas, H. M. Kalckar, M. J. Johnson, Van R. Potter, H. G. Wood, R. H. Burris, C. H. Werkman, P. W. Wilson, F. F. Nord, Ephraim Shorr, A. E. Axelrod, Frederick Bernheim, E. S. G. Barron, Frederick J. Stare. Pp. xii+281. (Madison, Wis.: University of Wisconsin Press, 1942). 3 dollars.

IT has been said by Sir Frederick Gowland Hopkins that among the most fundamental of the dynamic chemical events related to life are the oxidations which yield energy to the cell. The study of the mechanism of cell oxidations does indeed seem to be developing into a main route to the understanding of the biochemical basis of life processes. This explains why so many biochemists are now devoting their energies to these problems, as the flood of individual publications shows. But whereas there are numerous excellent compilations on other similar fields, such as the vitamins, for example, collected opinions on respiratory mechanisms are comparatively few, and mostly the published accounts have been presented in support of one particular point of view.

The University of Wisconsin is therefore to be congratulated on having made a highly successful venture to fill this gap. With the University of Chicago, it inaugurated on September 11–17, 1941, a conference to consider the respiratory enzymes and the biological action of the vitamins. The lectures and discussions on respiratory enzymes given at Wisconsin have now been published in book form, and may be cordially recommended as a valuable guide to the present state of knowledge in this highly complex field. It is worth mentioning that no less than twenty-seven main contributors take part, almost all Americans or those for whose presence the scientific life of the United States is the richer and that of Germany the poorer. All are scientific workers of distinction in this field. This is not necessarily a guarantee of a successful symposium; but in this case the combination leaves little to be desired. Whether due to the genial atmosphere of Wisconsin, or to skilful though anonymous editing, the views of the various contributors are expressed with conspicuous clarity and forthrightness, and the text, not being encumbered with experimental or mathematical detail, is most readable. Sometimes the contributions overlap a good deal; this would be very irritating in a text-book, but this is essentially a book for the research worker and advanced student, and such are more likely to be inspired by its enthusiasm than put off by its lack of continuity in presentation.

On the whole it is rather surprising to find so much agreement on fundamentals. This would have been unthinkable only fifteen or twenty years ago, and is an indication that the subject of tissue oxidations is growing up, and leaving behind the controversial and uncertain. The points now at issue are for the most part concerned with the relative importance to be given to various alternatives, rather than with factual disputes. Much of this clarity is due to the application of physicochemical methods. E. G. Ball, of Harvard, gives a valuable review of the cytochrome-oxidase cytochrome system, and shows how the energy of oxidation instead of being explosively liberated is released in a series of at least six steps, the amount at each stage corresponding with the oxidation-reduction potential of the particular enzyme system concerned. Not only these potentials (except that of cytochrome oxidase) but also the amounts of the various catalysts in different cells and tissues are now known. Dr. Ball charts these potentials and gives an ingenious theory of respiratory poisons. Final elucidation seems to await the isolation of all components, particularly of cytochrome *b* and cytochrome oxidase, which it is necessary to remind ourselves are as yet available merely as crude suspensions of ground-up tissues. In later chapters E. Stotz discusses the detailed properties of the cytochromes, and K. G. Stern gives an excellent comprehensive account of oxidases, peroxidases and catalases. Among outstanding controversial issues needing clarification, is the question of the indispensibility claimed by some workers for the presence of oxygen for catalase activity, which is well reviewed by Stern. In other chapters the Pasteur effect is constructively discussed by F. Lipmann, and the individual nicotinamide and flavoprotein systems are described; T. R. Hogness gives an account of the important link between the single-electron cytochrome systems and the two-electron reduction of the nicotinamide coenzymes which is provided by the flavoproteins, particularly by cytochrome *c* reductase. These compounds seem to be able to do this by virtue of their semiquinone formation.

Metabolic cycles always seem to give trouble. It is noteworthy that the Szent-Györgyi system of hydrogen transport, which until recently occupied a commanding position in all discussions, has to some extent receded into the background. In the first place, rival schemes, particularly the Krebs citric acid cycle and the discovery of carbon dioxide fixation in pyruvate metabolism, seem to have provided new and attractive alternative interpretations of some of the basic experiments of Szent-Györgyi, although Krebs himself has upheld the importance of this system. Secondly, hydrogen transport to the cytochrome system is now considered possible directly via flavoprotein from several intermediate metabolites, so that the same insistence on the essential transport by the succinate system does not seem to be regarded as necessary. A highly critical attitude towards the 4-carbon acid system is often noticeable, particularly by Hogness (p. 143) and Ball (p. 35); the latter rejects entirely as "a blind alley" the inclusion of the malate-oxaloacetate system into Szent-Györgyi's scheme. Whether the Krebs cycle really includes citric acid, or rather *iso*citric acid or some other intermediate is also debated. The application to bacterial metabolism of these cycles, and the importance in bacteria of carbon dioxide fixation, are discussed in valuable contributions from H. G. Wood and C. H. Werkman.

How, and to what extent, is this energy harnessed for use by the living cell ? The positive evidence in this most difficult question seems to be limited to the part played by coupled phosphorylations, as exemplified by the obligatory coupling between the oxidation of triose and the phosphorylation of adenosine diphosphate. H. M. Kalkar and C. F. Cori individually discuss these and related problems. The latter shows how the phosphorylation of glucose depends on the aerobic formation of energy-rich phosphate bonds during the simultaneous oxidation of substances such as pyruvic, fumaric and succinic acids. The glucose so phosphorylated is now capable of breakdown to triosephosphate and pyruvate, and thus the cycle of glucose oxidation continues. In reviewing these important mechanisms, Cori directs attention to the fact that in the intact cell regulatory arrangements must exist integrating these activities; such regulators may well include many hormones, substances which do not themselves appear to be essential constituents of any enzyme system, but which may perhaps soon be fitted into this fascinating story. Another example of aerobic phosphorylation is provided by F. Lipmann, who shows that in the bacterial oxidation of pyruvate the highly unstable acetylphosphate may be isolated as the silver compound. Otto Meyerhof, now of the University of Pennsylvania, contributes a stimulating introductory article on intermediary metabolism, which includes numerous valuable suggestions for present-day attack.

Space does not permit more than a passing reference to the discussion on tumour metabolism : the reviewer is here on delicate ground, for the phrase "most authors agree . . ." which occurs several times in this chapter is perhaps an over-statement. But this section is worthy of serious study, and the pessimism of K. A. C. Elliott is well offset by the exuberance of Dean Burk. The latter boldly challenges all and sundry that he will diagnose tumour growth from its metabolism correctly in well over 95 per cent of cases, but perhaps this estimate of the accuracy may be lowered if many more normal tissues with "cancer-like metabolism" are discovered, and several are already known. No one seems to have given much attention in this section to the possible connexion between aerobic glycolysis and insufficient oxygenation *in vivo*, although Lipmann in his discussion on the Pasteur reaction has done so, and this may in the reviewer's opinion be as important a factor in tumours as it is believed to be in other tissues with aerobic glycolysis, such as cartilage, medulla of kidney, and intestinal mucous membrane.

Although there is much about carbohydrate oxidation and something about amino-acid oxidation in this book, the oxidation mechanisms which deal with fats, aceto-acetic acid and fatty acids are scarcely referred to at all.

The text is enlivened by numerous "candid" photographs of the participants. The general production is excellent.

F. DICKENS.

A RUSSIAN-ENGLISH DICTIONARY

New Complete Russian-English Dictionary (New Orthography)

Edited by Dr. Louis Segal. Pp. xii+965. (London : Percy Lund, Humphries and Co., Ltd., 1942.) 42*s*.

THE making of dictionaries is an evolutionary process; each new dictionary has or claims to have certain advantages over its predecessors that justify its appearance in the competitive struggle for existence, while the greater part of the reading matter must necessarily remain unchanged. The most obvious merit of Dr. Segal's dictionary, in comparison with earlier Russian dictionaries, is the clearness of the type; this is a most pleasing improvement. The use of the new orthography is an inevitable development which will be welcomed by the ever-increasing number of those who are unacquainted with the old, and the accenting of the Russian words will also be a help to the average English user.

A characteristic of many of the older Russian-English dictionaries is the frequent use of obsolete English words, as though the compiler (usually a Russian) of the dictionary was himself unacquainted with the evolution of the English language in the last two centuries and had slavishly copied earlier lexicographers whenever a difficulty or doubt as to the meaning of a word had arisen. It must be admitted that this most recent dictionary displays the same characteristic of archaism, the origin of which can easily be traced to earlier dictionaries, particularly Alexandrov's, to which the author acknowledges his indebtedness, and in which identical archaisms occur. Words like "eliquation" and "prase" defeated both the reviewer and the "Concise Oxford Dictionary"; one finds words such as "tetraphyllous" where "four-leaved" would obviously have been better, and so far at least as agriculture is concerned some of the translations betray a certain limitation on the compiler's knowledge of English agricultural terminology. Taking the dictionary as a whole, these are quite minor defects; the point is that they all occurred in the old, pre-Revolution dictionaries and have been incorporated unamended into the new. On the other hand, the translated idioms have been considerably increased in number (in comparison with the older dictionaries) and have been brought up to date.

It would have been advantageous to the majority of English students of Russian to have had some simple guide to the conjugation of verbs included in the brief section on grammar at the beginning. This is a part which might profitably be extended in a subsequent edition.

FIRST SIR JOSEPH J. THOMSON MEMORIAL LECTURE

WITHIN the generous curve of Faraday's horseshoe table at the Royal Institution, almost every distinguished man of science has stood, at some time or another during the last hundred odd years, to deliver a "Friday Evening", or some other discourse. Some have been grim, and some have been gay, but none have been both in perhaps quite the same sense as Sir Joseph John Thomson.

The recent memorial lecture, under the auspices of the Chemical Society, given on April 16 from the same spot by the son of his predecessor in the Cavendish chair at Cambridge, is no ordinary tribute. Lord Rayleigh has produced something at once personal and vivacious, but at the same time historical. Three parts, very unequal in length, but all valuable, may be discerned. The first is biographical and completely charming. (Who can possibly forget 'J. J.' pushing his glasses up on to his forehead to look at something close at hand ?) The second is, in effect, largely an account of the search for the electron, and contrives to make the period 1870–1905 live again in retrospect. The third and shortest, depicts 'J. J.' as Master of Trinity. Many perhaps will wish that it had been longer, but for all that, one is glad to have it just as it is.

Our task now, however, is to meditate afresh upon the thirty-five years of activity to which Lord Rayleigh devotes the bulk of his address. Nevertheless, it is scarcely feasible to do this, without first of all recognizing the extraordinary intellectual strength possessed by the Cavendish professor. This characteristic is well brought out ; day after day he would go his rounds of some three dozen research students, hearing their individual troubles and setbacks, but ready almost immediately with counsel and answer to their problems. Lord Morley once remarked, "Never say never"; certainly tradition has it that 'J. J.' never required any "notice of that question". Doubtless, in such an atmosphere as this came into being the powers of the Cavendish Laboratory—and all that it stands for, even apparent neglect not excepted—to train men for research.

Lord Rayleigh deliberately limits himself to discussing the era already indicated ; but more than this, he bids us look at it with the eyes of those who were in it and about it. This is most salutary. At once, the value of such an approach is manifest, for it enables the great controversy of the times concerning the nature of cathode rays (corpuscular or wave-like ?) to be apprehended as it appeared to contemporary thought. Since then, there has been much uncertainty, both in principle and in detail. But in those days, nothing blurred the sharp outline which divided the two schools. Cathode rays had to be one thing or the other.

There seems little doubt that what imparted the initial impulse to these investigations was the feeling that in a highly rarefied gas conditions were likely to be less complex than in liquids and solids. The kinetic theory, too, was at hand to help in getting a clear view in the mind's eye of what exactly was happening. Hittorf apparently was the first to observe phosphorescence around the cathode. Meanwhile, broadly the British school—Varley, Crookes, Kelvin, to whom should be added George Francis Fitzgerald—upheld the corpuscular theory, whereas Lenard, Hertz and others on the Continent supported the wave-nature interpretation. Lenard showed that cathode rays could penetrate a thin aluminium window. This was something of a reverse for the corpuscular upholders, but Thomson inclined to the opinion, Lord Rayleigh says, that an explanation might be found in the generation of a derived stream of particles on the far side. In 1895 Perrin performed his well-known experiment (somewhat akin to Faraday's ice-pail) and Thomson made a crucial extension to it. In these ways it appeared inescapable that cathode rays were in fact transporting negative electricity, and were thus essentially particles. The final stages, leading up to (m/e), need no recapitulation here.

It is noteworthy that Thomson was always somewhat attracted by the border-country between physics and chemistry ; indeed a dissertation having a strong sympathy in that direction won him his fellowship at the first attempt. Seen at this angle, it is more than fitting that such a lecture as we are now considering should have materialized under the ægis of the Chemical Society. Perhaps with this in view, Lord Rayleigh dwells almost exclusively upon his subject's distinction as an experimenter. But Thomson's contributions to mathematical physics were no less remarkable ; for example, the discovery in the early 'nineties of electromagnetic momentum. In this may be seen a pre-condition for the rise of the great edifice in recent years, associated particularly with the names of Born and Dirac. Altogether, truly a momentous achievement. Then in 1918, on the advice tendered by Mr. Lloyd George to the Crown, 'J. J.' left the Cavendish for Trinity Lodge, there to gain new affections and new triumphs of a different kind ; and so it was, until the end came on August 30, 1940, in his eighty-fifth year.

F. IAN G. RAWLINS.

CYTOLOGICAL CRITERIA OF MAMMALIAN ENDOCRINE ACTIVITY

By C. L. FOSTER

Department of Biology, Middlesex Hospital Medical School

A CONSIDERATION of the development of endocrine histology throws considerable light both upon the problems which have confronted the investigator and the way in which attempts have been made to solve them. When the physiological significance of the endocrines was less understood than it is now, their histological descriptions were relatively simple. For example, in the anterior lobe of the pituitary two chromophilic and one chromophobic type of cell were described. As the gland came to be investigated in the light of an increasing knowledge of its physiological activities and with improved techniques, the complexity of the histological picture increased. Transition cells between chromophobe and chromophil have been recognized in many animals investigated[1,2,3], and in the dog[4] dark and light varieties of the basophil cells have been described, as have special carmine acidophils in the cat[5]. In a like manner, the original principal and oxyphil cells of the human parathyroid[6,7] have each been divided into two types—dark and light ; osmiophilic and non-osmiophilic cells have been described in what was originally considered as the uniform parenchyma of the rat parathyroid[8,9], and I[10] have observed a somewhat similar differentiation with intermediate cell types in the mouse. Again, in the human pancreatic islets Gomori[11] has recorded cells intermediate between *A*-cells and the *D*-cells of Bloom, and Hoerr[12] and others have described dark and light cells in the zona reticularis of the adrenal cortex.

The attempts to explain the apparently increased histological and cytological complexity of various endocrines have resulted again in an effort at simplification. The present tendency is to discover whether the apparently different cell types of a gland are not in reality phases of a cycle associated with secretory activity. This concept has focused attention on individual rather than mass cellular changes within the gland, and has opened up what may become a more profitable approach to the subject—that of physiological cytology.

The more specifically cytological attitude to these problems has resulted naturally in a search for reliable criteria of cellular activity. Of these the most obvious were the stainable intracellular granules, such as those of the acidophil and basophil cells of the anterior pituitary, which, largely by analogy with the specific granules of the pancreas and similar exocrine glands, have come to be regarded as prosecretion granules, and hence their density in a cell has been looked upon as a function of its secretory activity. Although this is a reasonable assumption and has so far proved satisfactory as a working hypothesis, there is as yet no histochemical evidence (at any rate for the anterior pituitary among endocrines) to support the identification of the granules with the secretion or its precursor. Somewhat similarly in the adrenal cortex—where there is evidence that the cortical cells originating perhaps from fibroblast-like cells in the capsule move radially through the cortex until they finally become senescent in the zona reticularis[13,14]—variations in the size and concentration of osmiophil droplets in the cells of the different cortical zones have been used as an index of cellular activity[15,16]. Similar correlations might perhaps be made with the phases of development and regression of the corpus luteum[17] in relation to its fat and lipoid content and physiological activity. As is pointed out later, there is some evidence derived from microchemical tests that the lipoid material in the adrenal cortex is in part associated with sterol compounds.

In addition to a consideration of these labile cell contents, interest has been increased in the permanent cell parts such as the mitochondria and the Golgi material. Enough evidence has now been produced to remove any doubts as to their real existence[18,19], but very little of a precise nature is known of their chemical constitution. Various workers have reported the mitochondria as containing, in addition to lipoids (of which there is but little according to Bensley[20]), protein[21], vitamin A[22], vitamin C[23] and glutathione[22]. A possible protein component has also been suggested for the Golgi body[19,24]. What little is known of these cell organelles is at present of little value in elucidating their role in secretory activity, but that the Golgi bodies do have a role is becoming increasingly evident. The topographical relation between the Golgi apparatus and the secretion products is not so clearly established in most endocrine as in exocrine gland cells, but there is some evidence for such a relation in the thyroid gland, where 'pro-colloid' droplets have been recorded in the Golgi area[25,26]. Nevertheless the close topographical association in the pancreatic acinus cell, for example, between the Golgi material and the neutral-red vacuome or prozymogen substance[19,27] has strengthened the concept of a similar relationship between secretory activity and the Golgi body in endocrines as well. Additional suggestive evidence is furnished by (1) Bowen's[18] demonstration that in certain animals the acrosome granule of the sperm originates in a vacuole which is in intimate contact with the Golgi material; (2) the observation of Severinghaus[28] and others[29] that the Golgi area (in anterior pituitary cells, for example) is often vacuolated, and (3) the fact that the walls, or the area in proximity to the walls, of the contractile vacuoles of certain Protista blacken with osmic acid[30].

A marked polarization of the Golgi body is generally a characteristic of exocrine gland cells, this structure being between the nucleus and the surface at which the secretory products are discharged. The only endocrine which shows anything like a fixed polarity is the thyroid, where the body is between the nucleus and the follicular lumen. Since the thyroid is by origin a gut diverticulum, and possibly only secondarily a gland of internal secretion, this is perhaps to be expected. Cowdry[13], however, maintained that the position of the Golgi body was a reliable index of the direction of secretory release, its occasionally reversed position in the guinea pig, for example, being indicative of secretion directly into the capillaries. This may be the case for the thyroid, but there is no satisfactory evidence in support of a fixed capillary polarity in epithelioid glands such as the anterior pituitary and parathyroid, where the observations are conflicting[19], or in the islet tissue or adrenal cortex. Thus the question of the polarity of the Golgi body in endocrines as a whole is at the moment too controversial to be admitted as evidence of its participation in secretory activity.

Since it has been established that in exocrine glands the Golgi body hypertrophies during secretory activity[18]—for example, in the parotid gland—the endocrines have also been examined from the same aspect. Generally speaking, activation results in hypertrophy of the Golgi body. This occurs, for example, in the thyroid gland after the injection of anterior pituitary extracts[32, 33], in pancreatic islet cells after œstrone injection[34], and in the rat parathyroid[35] after the experimental induction of low calcium and low phosphorus rickets respectively. Similarly, there is some evidence to show that inactivation of a gland may result in a shrinkage of the Golgi body; this, for example, has been reported in the rat parathyroid after parathormone injection[8]. Whether, however, Golgi body hypertrophy or its reverse is to be correlated with a corresponding increase or decrease of secretion formation, with secretion release, or with both, is by no means certain.

The anterior lobe of the pituitary gland provides the most satisfactory material for an analysis of this problem, since there are records not only of the state of granulation of the chromophil cells in relation to physiological activity, but also of the condition of the Golgi material. Severinghaus[3], on the basis of the study of human material stained under carefully controlled conditions, has produced evidence to show that, both in acidophil and basophil cells, there is a regular cycle of granule depletion ending in a chromophobic state, followed by a granule accumulation resulting in the restoration of the chromophilic condition. This process continues, presumably, until the cells become senescent. Thus, the state of complete granulation is to be regarded as a phase in a cycle which marks the end of synthesis and the beginning of secretory release. This fact needs to be established in other animals; Kirkman[1], for example, working with the guinea pig, was able to trace the stages in the degranulation of the basophil cells as well as their development from small chromophobes (as was Severinghaus[2] in the rat), but the mechanism of granule replenishment was not determined.

Apart from these observations, there are no others similarly based on staining reaction sufficient to disprove an alternative interpretation of the functional nature of the granulated chromophil cell. It could be argued that the granules represent merely a surplus prosecretion, so that if synthesis and release proceed at the same rate there will be no change in the degree of granulation, and degranulation will be due to a temporary increase of release over synthesis. Should this be the actual state of affairs it would imply that granulated as well as degranulating cells may be actively releasing hormones and consequently the interpretation of variations in the histological composition of the gland in relation to its activity would become a problem of extremely great complexity. These matters in relation to the activity of certain exocrine glands have been considered in some detail by Hirsch[36].

Further light, however, is thrown on this subject when the relation of the degree of granulation to the state of the Golgi body is considered. If the evidence already cited (and it is only a small part of it) justifies the assumption that increased secretory activity—whether of synthesis, release, or both—is associated with Golgi body hypertrophy, then the Golgi bodies of any cells in an active secretory state, whether granulated or degranulating, should show some degree of hypertrophy. An examination of the records of glands specially impregnated to show the Golgi material definitely gives the impression that there is no hypertrophy in fully granulated cells. This is further emphasized by the fact that it has been shown that the 'typical', that is, fully granulated, acidophils and basophils of the rat have characteristically shaped Golgi bodies readily distinguishable from each other[2].

Similar observations have been made for the cat by Atwell[37]. These differences would probably have been difficult to establish had there been any considerable hypertrophy together with a secretory activity existing in such granulated cells, for such a condition would presumably have tended to reduce the morphological differences between the two Golgi types. It might, of course, be argued that secretory activity in the normal anterior pituitary is not associated with any marked Golgi body hypertrophy, that produced by experimental methods such as the injection of œstrogens being an abnormal state due to over-stimulation. Hagquist[38], however, studying the cytological changes in the anterior pituitary of the female guinea pig during its reproductive cycle, has reported a loss of granules in both types of chromophil cell as occurring about the eighth day of the cycle, accompanied by a marked and progressive hypertrophy of the Golgi material. Such a rhythmic process indicates that hypertrophy during secretory activity is characteristic of the Golgi body and supports the conclusion that the cycle of the chromophil cells is essentially one of alternating granule accumulation and granule loss.

In addition, it may be noted that in glands where there is no reason to believe that activity is markedly rhythmical, such as the pancreatic islets[39] and the parathyroid[8,10], the Golgi body is found to present varied configurations indicative of varying states of activity in the same gland. Therefore from such evidence as has been presented it may reasonably be inferred that in the anterior pituitary, and probably in the thyroid, parathyroid and pancreatic islets, secretory activity is associated with Golgi hypertrophy even under normal conditions. There is, of course, the possibility that in the islet tissue variations in the Golgi body morphology may be associated with the different cell types, but this is a question yet to be investigated.

The relation of the Golgi body changes to the two phases of secretory activity is more difficult to determine, and most of the available data again relate to the anterior pituitary. Theoretically, the best approach to this problem would be to investigate the effect of slowing down or stopping experimentally one or other of the two phases. There is evidence that in the female rat heavy doses of œstrogens inhibit the release of gonadotrophins, since atrophy of the ovaries results[40]; yet the cytological picture is one of great activity—degranulated cells and hypertrophied Golgi bodies[29, 28]. Presumably in this case a state of exhaustion has been produced resulting from a stimulation of secretory release far in excess of synthesis. This at first sight suggests a correlation between the Golgi material and secretory release. There is no proof, however, that the greatly enlarged Golgi bodies may not have been correlated with an initial increase of synthetic activity and afterwards maintained by an even greater secretory release. In other words, it still allows of the possibility that Golgi hypertrophy is associated with both phases of activity.

Gonadectomy in some animals produces changes which some have considered as being in part antithetic to those resulting from œstrogen injections. In the rat, castration results in two distinct changes, the one being an increase in the proportion of basophils, due according to Pomerat[41] to an increase in mitotic activity of the pre-existing basophils, the other the appearance of characteristic vacuolated castration cells. Similar changes have been reported in rats after artificial cryptorchidism[42, 43] and in dogs after the injection of canine antihormone[44]. It has been suggested by Severinghaus[28] that castration vacuolation might be due to a granule solution resulting from an augmentation of secretion production and an inhibition of its release. If this is the case, as seems reasonable, the hypertrophy of the Golgi material during the early phases of vacuolation (for there is a regression later on) suggests that it is associated with secretion production. But, again, there is no proof that castration does not involve an initial transitory increase of secretory release. Finally, in describing the transition from the inactive small chromophobes to the basophils in the guinea pig, Kirkman[1] records that, just prior to the appearance of the granules, the Golgi body hypertrophies and the mitochondria become scattered, and Hagquist[38] for the same animal indicates that there is some hypertrophy during the process of granulation in chromophils, although the maximum is attained during degranulation, where there is also the greatest mitochondrial dispersion. Thus the scanty data available do not permit of any conclusion, but suggest that the Golgi body is involved in both phases of secretory activity. The thyroid gland contributes little to the elucidation of the precise role of the Golgi body, because its study is complicated by the problems of colloid release from the follicles, in which the Golgi material may also participate.

In regard to the function of mitochondria in secretion, an increase in their number is associated, for example, with the degranulating chromophil cells of the anterior pituitary of the rat[28] and guinea pig[1] during pregnancy, and after œstrone administration in the rat[28]. It has also been noted previously that changes in the mitochondrial dispersion in relation to the state of granulation occur in the guinea pig. In the thyroid, Okkels[33], and Bailiff[26] observed a massing of mitochondria in the apical poles of the cells following upon the stimulation of secretion into the follicular lumen. Okkels[33], from his observations, suggested that the mitrochondria acted as condensers of the secretion. Other workers have recorded changes in the mitochrondrial morphology of the thyroid, following upon experimental treatments. Seecof[45], and Cramer and Ludford[25] described a filamentous condition resulting from stimulation induced respectively by partial thyroidectomy and low temperature. The same workers observed a conversion into a granular state consequent upon a reduction in cellular activity. These observations certainly indicate that the mitochondria have a role in secretory activity, but there is insufficient evidence to show its precise nature.

Finally, in the adrenal cortex there are no records of changes in the mitochondria and Golgi material which could be correlated with secretory activity. There is, however, evidence to show that when the activity of the cortex is stimulated experimentally, by exposure of the animal to cold, for example, there follows an initial increase of lipoid material followed by a decrease, as the stimulation is maintained. Flexner and Grollman[16] regarded this initial increase of lipoid as being indicative of increased activity. On the other hand, Dosne and Dalton[15], interpreting similar results, regarded the initial increase as a kind of compensation reaction, further increase in activity being accompanied by lipoid loss. This interpretation is supported by the investigations of Bennett[47], who has produced evidence which indicates that the adrenal cortex of the cat may be conveniently divided into four zones, on the basis of their lipoid content, and on their reaction to a histochemical test designed to show the presence of the keto-groups of the cortical sterones. He found that the reaction was practically confined to that zone of the cortex (consisting of part of the zona fasciculata) which is richest in lipoids—this he called the secretory zone. Since it was found also that removal of the lipoid with suitable solvents resulted in an inability to detect the keto-groups, he concluded that there was probably an intimate relation between the two, so that if stimulation of the cortex brings about a rapid release of the cortical hormone, the progressive disappearance of the lipoid droplets is thus to be expected.

AGRICULTURAL RESEARCH INSTITUTES AND THE FUTURE

By Dr. B. A. KEEN, F.R.S.

THE organization and administration of agricultural research, in common with many other national activities, will receive critical—and, it may be hoped—constructive attention as a result of the War. Although the post-war structure of our agriculture cannot yet be predicted with confidence, considerable changes will probably occur, which should be accompanied—and so far as possible, anticipated—by appropriate new perspectives in the agricultural research, advisory and teaching organizations.

This article deals primarily with research and is further restricted to arable agriculture. Although other branches, such as animal husbandry and economics, also have their own vital problems, it is not likely that their framework of organization and administration will need to be vastly different from that proper to research in arable agriculture. Indeed, there are so many problems requiring joint examination that some organization to serve those needs that are common to all branches is not only desirable, but also essential.

If one looks back at, say, the last hundred years of research in arable agriculture, a clear pattern can be seen, especially in Great Britain. There have been two well-defined stages, the second of which is already changing into a third. The picture is one of orderly and progressive development, and the third stage is a logical outcome of the second.

It so happens that the history of Rothamsted well illustrates the sequence. The first stage—the era of Lawes and Gilbert—was a frontal attack on a problem of practical agriculture: the manuring of crops. The method was one of simple and direct field experiments; the function of the laboratories was to produce a mass of expository analytical data on the soils and crops. It is true that valuable novelties were employed in the method of approach: the problem was detached from its context of crop rotations and agricultural systems by growing each crop continuously. The method well served its purpose, for it was quick, and it not only gave striking new information on crop nutrition but the field results were capable of immediate application to practice. The effects of artificial manures on crop yields were so large that they were not wholly obscured even by widely different soils, climates, and agricultural systems. Lawes and Gilbert took little or no direct part in the repetition of their experiments in other areas. Examination of the increasing mass of the Rothamsted data occupied the greater part of their attention; for very many years Gilbert was absorbed in the nitrogen balance sheet for the various plots and in the amounts of nitrogen that could not be accounted for when the analyses of soil, manure, crop, rain and drainage were put together. Had the study of soil microbiology been as well forward then as agricultural chemistry some of the puzzles would have been clearer. However, the important point was that the conclusions and their technical corollaries might have only a local validity; but the full realization of this was to come only later. The effort, in fact, was somewhat like an attempt to make a synoptic chart for our variable continental-seaboard weather from very detailed meteorological observations taken at a single station.

With the deaths of Lawes and Gilbert the first stage of agricultural research closed. The Rothamsted work had shown that agricultural science had extended beyond the scope of any one man. The need for the help of a microbiologist in a problem that began in chemistry has already been mentioned; and, while biochemistry could advance the frontier of agricultural chemistry, it was, in turn, handicapped by lack of knowledge of the physical environment in the soil. Clearly, the help of research workers in many branches of science was needed if soil and plant relationships were to be further elucidated. This second stage of agricultural research began with modest resources, but the Development Commission, and especially the War of 1914–18, gave it a great impetus. It has now been running for some twenty years in substantially the form planned by its designer, the late Sir Daniel Hall. Weaknesses and merits have had time to show themselves, so a review of the organization is appropriate, the more so in view of the many war and post-war agricultural problems.

In this article it is unnecessary to set out the achievements of the second phase of agricultural research. To any unbiased observer they must amply justify the faith of Hall's vision, for the boundaries of agricultural science have been greatly enlarged. To take only one section, a comparison of the original 1912 edition of Russell's "Soil Conditions and Plant Growth" with the seventh, of 1937, shows in striking fashion how far we have travelled in twenty-five years and how much British agricultural scientists have contributed to that progress. The annual reports and papers published by other research institutes—those dealing with market gardening and fruit growing, for example—show equally striking advances in their own spheres of work.

It is important to study the organization under which this work was done. There were some obvious difficulties to overcome: specialists tend to work in water-tight compartments, and few of the new men were likely to have any agricultural background. Thus there was the double problem of fostering team-work so that the new agricultural science should be a coherent whole, and of providing a suitable environment to ensure that technical applications of the scientific advances would not be missed or ignored by the research workers.

Superficially, one single large research institute for the whole of agricultural science would have seemed the solution, but for two inescapable facts: first, agricultural research embraces such widely different activities as animal nutrition, farm economics, plant genetics, and soil physics; and second, effective central direction of research, whether by a director or a committee, is impossible if the number of workers exceeds a certain limited figure. The alternative adopted was a number of smaller institutes, each of which took an agreed broad section of agricultural research as its main concern. A possible looseness of contact between these sections was less important than the reasonable certainty that within each section team-work would build up a coherent picture. Another far-seeing provision was to give each institute the widest freedom of control over its own research programme, for the reason that decentralized control works best. In the past twenty-five years many members of the institutes have studied the organization of agricultural research in other countries, and many overseas visitors have examined our scheme; the almost universal opinion is that none is better than ours and most are less effective.

Nevertheless, no one, least of all those in the research institutes, would claim that the present organization should be continued unchanged merely because it has been successful in the past. Should they be consulted about their own future—and it is to be hoped that they yet will be—it would assuredly be found that those concerned with arable agriculture are anxious that the third stage of agricultural research should be organized, for its pattern and requirements are already quite clear.

The very advances of the second stage showed that many technical conclusions obtained for one soil, climate and agricultural condition were either invalid, or needed modification, elsewhere. To meet this difficulty some of the institutes had built up chains of experiments as best they could. The problems investigated were necessarily restricted, as only the simplest field procedure could be used. Their scope was further limited because the problems had to be those of immediate interest to official or private organizations able to meet some of the costs and to help in securing sites. Although the experiments were simple, incomplete, and beset by various difficulties, they were amply justified by their results both in agricultural science and practice. The overriding needs of war-time agriculture have removed, for the time at least, some of the difficulties: contacts with other institutes and advisory officers are increasing, and an informal network of co-operative field experiments (and demonstrations) is developing. For the first time there emerges a possibility of joint work on some important agricultural problems not included within the interests of official and private organizations.

The freedom of development that characterized the second stage of agricultural research has not only produced the third stage as a logical outcome: it has also provided the technical machinery that makes the next stage possible. The statistical design of experiments to secure comparable results of an ascertainable degree of accuracy enables the maximum of information to be obtained from a given amount of experimental effort, by combining several related questions in one design. Thus, problems concerning two or more research institutes could be dealt with in the same experiment. Such a scheme of field experiments would need co-operative control by the interests concerned through a committee which might work under the ægis of the Agricultural Research Council. The committee would be responsible for selecting the programme from the various proposals put forward and for combining the selected problems in the most economical manner. Each experimental site would be typical of an important soil and farming system.

It is certain that a system of well-distributed replicated experiments will be of the utmost value to the research institutes. It is equally certain that it will enable rapid answers to be given to many urgent post-war agricultural problems of a practical and economic nature, for, as already stated, it is growing up even now under the compelling pressure of immediate war-time problems.

Wars and their aftermaths are conducive to centralized control of many activities. The majority of research workers regard such controls as temporary necessities which have an unfortunate tendency to persist after the need for them has vanished. Lest it should be thought that the scheme outlined above is merely another fashionable war-time centralization, it is desirable to stress the following points: the need for it was apparent before the War; it is a natural development from a second to a third stage of agricultural research. Finally, it does not call for any significant changes in the control and administration of the research institutes. Their record during the twenty-five years of the second stage of agricultural research, and the fundamental work now in hand and projected, are enough to show that they are still efficient instruments in the furtherance of agricultural science.

As stated at the outset, this article deals only with the organization and administration of research in arable agriculture. Contacts with colleagues in various other branches lead me to believe that among agricultural research workers there is general agreement on the situation briefly discussed here and on the best method of dealing with it. But agricultural science ranges so widely that workers in other branches will have their own proposals to offer for the general plan of research organization. One purpose of this article is to promote discussion in these columns and elsewhere, in the belief that a common ground of agreement will emerge; there is no doubt that, especially at the present time, such discussions and expressions of opinion will be very opportune.

OBITUARIES

Dr. Arnold Berliner

The death occurred, on March 23, of Dr. Arnold Berliner, well known to the scientific world as the founder and editor of *Die Naturwissenschaften*.

Berliner belonged to the first generation of 'technical physicists' and worked in close connexion with Emil Rathenau as head of the physics laboratories of the A.E.G. during the period of rapid expansion of this firm. The development of the incandescent carbon lamp and of X-ray bulbs owes much to him—he introduced the first 'getter', phosphorus, in the manufacture of lamps, and the large scars on his arms bore testimony of the early stages of experimenting with X-rays when their dangers were not yet realized. Among other technical problems advanced by Berliner was that of the phonograph: he was the first to introduce the disk form for records (1889).

As an author Berliner was successful with a textbook on physics which appeared in several editions. It is conspicuous for stressing the application of physical knowledge to technical problems, many years in advance of a recognized 'technical physics'. In "Physikalisches Handwörterbuch", edited by Berliner and Scheel, many of the articles defining concepts or describing methods used in physics are from Berliner's pen.

These and other literary products, sound as they are, have not attained the importance of Berliner's creation of *Die Naturwissenschaften* in 1912. Framed on the model of NATURE, for the achievements of which Berliner had the greatest admiration, this journal for general science was to draw closer together the physical and the biological, the experimental and the descriptive sciences. Berliner addressed himself mainly to the then young generation of men of science. Much of the success of the journal was due to Berliner's vivid personality, his close contact with the majority of young physicists and mathematicians and his initiative in formulating the subject of articles he wanted written for his journal. Thus *Die Naturwissenschaften* became a mirror reflecting the development of science during 1913–30. To what extent the success of the journal depended on its editor became apparent when his work became limited by a serious eye trouble which made reading nearly impossible to him for many years. His field of vision was filled with a misty haze; after having vainly consulted many oculists, Berliner found the physicists' solution of eliminating much of the light diffusely scattered in his eye by filtering away the short-wave part of the spectrum and reading by red light only.

Berliner's desire was to complete the twenty-fifth volume of *Die Naturwissenschaften*, his very own creation. In the "Aryanization" of the publishing firm of Julius Springer, the old man was turned out of his office in 1935. He had since lived a life of reminiscence of his many friends—artists, men of science and politicians. Various attempts to find a new home outside Germany were unsuccessful. Now his friends deplore in his tragic escape from life the loss of one who represented much of the best cultural traditions of a bygone Germany, and of a warm-hearted and helpful friend. P. P. EWALD.

DURING the years following the War of 1914–18, Arnold Berliner was a prominent figure in German science. There was no Naturforscher-Versammlung and no meeting of the Physikalische Gesellschaft where his small but powerful figure with the characteristic beard and big spectacles did not appear, no scientific conference where his wise counsel was not welcomed. He never claimed to be a man of science, but only a "poor technician". But he insisted that every article in *Die Naturwissenschaften* should be written in such a way that his "simple mind" could understand it. How few of the contributions proved up to the high standard which he set, and how lively was the ensuing correspondence! He had a collection of the most remarkable extracts from these letters, as material on the "psychology of the scientist", whom he liked to describe as "mimosenhaftes Stachelschwein" (a hybrid of mimosa and porcupine). Perhaps he did not realize how well this description fitted his own character, which was the strangest mixture of infinite kindness, generosity, greatness of outlook and personal touchiness.

He was a technician by profession, an amateur scientist; but his real life was in literature, art and music. He read abundantly and remembered everything. He knew all the great galleries of Italy and Germany, and filled his home with good modern pictures. But his greatest pleasure were his annual visits to the Bach, Beethoven, Brahms festivals and to Bayreuth. Of his numerous friendships with men of importance he valued none higher than that with Gustav Mahler, the composer. Music was left to him when the decay of his eye-sight deprived him of reading and enjoying art. Finally, even music was taken from him, for going to concerts became impossible for a Jew. The work of his life was broken and his last years were lonely, dark and tragic. Many of his friends were dispersed over the globe. But he will not be forgotten by them. MAX BORN.

Prof. A. L. Selby

ARTHUR LAIDLAW SELBY, born on July 2, 1861, at Atherton, Lancashire, was the eldest son of Atherton Thomas Selby. He was educated at Heversham Grammar School and at Queen's College, Oxford. He was a fellow of Merton College from 1886 until 1893, and examiner in the Honour School of Natural Science in 1889–90 and 1900–1. He married Dorothy, daughter of Ernest Beck of Great Amwell.

After holding an assistant demonstratorship in physics at the Clarendon Laboratory, Oxford, for six years, Selby was in 1890 appointed assistant professor of physics at Cardiff University College, becoming professor of physics in 1897. He occupied this chair for twenty-nine years, retiring in 1926 with the title of professor emeritus. During his sixteen years of retirement he continued to reside in Cardiff, and maintained the closest possible touch with the College. He died on July 22 last, at the age of eighty-one. He is survived by his widow.

It would be vain to attempt in a short obituary notice to do justice to the manifold services rendered by Selby to the University College at Cardiff, to higher education in Wales, and to the many students who have passed through his department. His personality, his clear and unbiased judgment, and his inimitable command of phrase, marked him as a leader in committee and as an inspiring lecturer in the class-room. His transparent honesty of purpose and his sympathetic understanding rapidly gained for him the confidence of his students and colleagues, and he never failed to win the lasting affection of those who worked with him.

His name will be perpetuated in the series of Selby Lectures, and will be held in affectionate remembrance by all who knew him. R. T. DUNBAR.

NEWS and VIEWS

Anglo-Soviet Scientific Collaboration Committee

IT is now four months since the formation of the Anglo-Soviet Scientific Collaboration Committee under the chairmanship of Sir John Russell. The Committee came into being as a result of a conference held last March at the Royal Society to discuss the development of contacts between British and Russian scientific workers. With Sir John Russell as chairman and Mr. J. G. Crowther as vice-chairman, the Committee arranged that scientific communications should be forwarded to the U.S.S.R. according to the following procedure. Letters addressed by individual British men of science to individual Russian men of science, or communications from British scientific and technical societies to the corresponding Russian societies, can be sent either to Sir John Russell, Ministry of Information, Malet Street, London, W.C.1, or to Mr. J. G. Crowther, British Council, 3 Hanover Street, London, W.1, who will take the necessary steps to forward the communications to the U.S.S.R. This amplified the machinery for exchange of scientific information with the U.S.S.R. already set up by the British Council.

A number of communications have already been forwarded to the U.S.S.R. in this way, but owing to the time taken in transit and the inevitable dispersion of Soviet scientific workers, and the evacuation of scientific institutions in the Soviet Union, it is realized that it may be some time before replies reach Great Britain. In collaboration with the University of London School of Slavonic Studies, the Committee has arranged for special Russian classes for scientific workers. In this way, many young scientists are being encouraged for a moderate fee to learn the Russian language. The Committee has fully realized the importance of a satisfactory exchange of scientific literature between Great Britain and the U.S.S.R., and as a basis for this has recommended that a survey shall be undertaken of the war holdings of Russian scientific and technical periodicals in Great Britain, with details of location and accessibility. The British Council has agreed to finance the survey, which will be organized by ASLIB. The survey is already under way, and it is hoped that it will be completed in two months time. Librarians of scientific institutions are now asked to co-operate in this important piece of work by completing and returning their questionnaires as soon as possible. When the survey is completed the Committee will endeavour to obtain from the U.S.S.R. the periodicals still being published in the Soviet Union, but which no longer reach Great Britain.

In view of the urgent demand for a Russian-English technical dictionary, the Committee is making a collection of existing glossaries of Russian technical and scientific terms in Great Britain and the United States, with the idea of placing a complete set in the Science Library in London, where they can be consulted. If at a later stage it should be found possible to compile a new Russian-English technical dictionary, these glossaries will form a valuable basis to work on. A location list of Russian technical dictionaries is also being compiled, and scientific workers are asked to assist in this by sending to the Secretary of the Committee a list of dictionaries in their possession. Several scientific societies and individual men of science have approached the Committee concerning the provision of a panel of Russian scientific translators. The Committee has already collected together the names of several qualified Russian translators, and is prepared to receive names of reliable translators for inclusion in the list.

What Constitutes a Nation ?

WHAT constitutes a nationality is as hard a question to answer as the allied one of what is denoted by the word race. J. R. Swanton, in *Smithsonian Institution War Background Studies*, No. 2, has presented the problem clearly in a manner the non-expert can readily grasp. Obviously many factors go to the formation of a nation: common physical type, geographical background, governmental unity, language, religion, economics, etc. But when the major cultures of the world, both past and present, are considered it will be found that no one of these is a dominant factor. There are true nations where the physical types are hopelessly mixed, as well as other factors which one would have thought vital to unity. On the other hand, even one of the more important criteria, namely, language, can fail to be a binding element—as witness England and the United States. Here, though the language is the same, no one can deny that there are two distinct nations. On the whole, the author seems to be driven back to the idea of the importance of voluntary associations of folk living under a government desired by the majority. This is, of course, difficult to test in the case of past civilizations, but seems to be applicable to modern nations. But if so it cannot be too much stressed, indeed it is the keystone of the theory, that what one nation may desire, in fact what may be the cement that makes it a nation, may not be at all what appeals to other agglomerations of men and women whose nationality will be determined by a totally different outlook on life.

Industrial Health Research Board

THE Medical Research Council has appointed the following to be the members of its Industrial Health Research Board during the period 1942–45: The Rt. Hon. the Earl De La Warr (*chairman*), Prof. F. C. Bartlett, Brig.-Gen. A. C. Baylay, Dr. J. C. Bridge, Dr. A. N. Drury, Dr. T. Ferguson, Dr. M. W. Goldblatt, Dr. A. Bradford Hill, Dr. Donald Hunter, Prof. Esther Killick, Air Vice-Marshal Sir David Munro and Mr. J. L. Smyth. Prof. A. W. M. Ellis, director of research in industrial medicine under the Council, will also attend all meetings. Dr. R. S. F. Schilling, one of H.M. medical inspectors of factories, has been seconded to the service of the Council by the Ministry of Labour to act as Secretary of the Board. The terms of reference of the Board have recently been revised and are now as follows: "To advise and assist the Medical Research Council in promoting scientific investigations into problems of health among workers, including occupational and environmental factors in the causation of ill-health and disease, and the relation of methods and conditions of work to the functions and efficiency of body and mind; and in making known such results of these researches as are capable of useful application to practical needs."

Jean-Baptiste Van Mons (1765—1842)

ON September 6 occurs the centenary of the death of the once famous Belgian chemist and horticulturist Jean-Baptiste Van Mons who died at Louvain in 1842 at the age of seventy-six after a life entirely devoted to science. Born in Brussels on November 11, 1765, when Belgium was under foreign domination, he lived to see Austrian rule give way to French and French to Dutch, and then in 1830 to see his country gain her independence. But under every regime Van Mons steadily continued his work and it was largely through his labours that discoveries made in France became known in the countries with which she was so frequently at war. By profession Van Mons was a pharmacist, but when twenty years of age he wrote an essay on the new principles of chemistry and he subsequently corresponded with Lavoisier, Fourcroy, Monge Hachette and others. By the French authorities he was entrusted with a survey of the Belgian mines and in 1797 was made a professor at the central school of the department of Dyle. On the invitation of the French chemists he assisted in editing the *Annales de chimie* and in 1801 founded the *Journal de chimie et de physique*. By his own contributions to these and to the periodicals of Gren, Crelle, Brugnatelli, Nicholson and others he spread abroad a knowledge of the work of such as Volta, Vauquelin, Fourcroy and Chenevix. He was the first to introduce vaccination into Belgium, and all his life he experimented on the improvement of fruit trees. When the Belgian Academy was revived in 1816 Van Mons was nominated to a seat and the following year he was made professor of chemistry and agriculture in the restored University of Louvain. This post he held until 1836. Of his sons, Louis-Ferdinand Van Mons (1796–1847) was one of the chief artillery officers of Belgium and Charles-Jacques Van Mons (1798–1837) was professor of pathology in the University of Brussels.

Francis Adams (1796-1861)

UNDER the title of "A Great Country Doctor", the June issue of the *Bulletin of the History of Medicine* contains a lively article by Prof. Charles Singer on Francis Adams of Banchory, the son of a village labourer who rose to be one of the greatest medical scholars of his age. His principal achievements were a translation of "The Genuine Works of Hippocrates" (1849), which Prof. Singer describes as "probably the most widely read of any work on medical history in the language"; "The Seven Books of Paulus Aegineta" (1844–47), which "retains to this day its position as far and away the finest venture in pure historical medical research in the English language"; and "The Extant Works of Aretæus the Cappadocian" (1853), which unlike the other two works contains the Greek text as well as the translation. His minor publications include articles to medical journals, translations of Horace and Musaeus into English verse, of Gray's "Elegy" into Latin, and of Wolfe's poem on Sir John Moore into Greek. He also collaborated with his son, Dr. Leith Adams, F.R.S., in a paper read before the British Association at Aberdeen in 1859 entitled "On Ornithology as a Branch of a

Liberal Education", and contributed to Dunbar and Barker's "Greek and English Lexicon" (1831), Lemprière's "Classical Dictionary" (1838), and Greenhill's "Theophilus" (1842). Adams was not only a great scholar but was also an excellent doctor. "His first love and his last", says Prof. Singer, was his practice, his patients and the poor." His devotion to his profession was best shown by his declining the chair of Greek at the University of Aberdeen, which afterwards gave him an honorary doctorate. He paid several visits to Oxford and London, where he made friends with many learned men, particularly James Quain and William Sharpey, the founders of the modern academic teaching of anatomy and physiology in England. Dr. Singer ends his fine essay by saying that though the ranks of general practitioners in Britain have produced many eminent men of science, such as J. A. Lockhart, Sir James Mackenzie and J. A. MacMunn, none of equal distinction as a scholar practised in so isolated a locality as Adams.

A Pilot-Channel Regulator for the 'K-1' Carrier System

VARIATIONS in attenuation of the cable conductors used for the K–1 carrier system are compensated by corresponding changes of gain under control of a pilot-wire regulating system. Since these changes in attenuation are due primarily to temperature changes, and since all pairs in the same cable are approximately at the same temperature, a pilot regulation system—in which the gain over the various pairs is adjusted to conform to the temperature of one pair of wires in the cable—is a simple and satisfactory way of handling the regulation. There are, however, certain minor deviations from pair to pair for which such a system will not provide, and with long circuits over, say, some five hundred miles, some additional regulation will be needed to take care of these residual deviations.

An article by J. H. Bollman (*Bell Lab. Rec.*, **20**, No. 10; June, 1942) describes a regulator using thermistors as controlling elements, supplementing the normal regulating system. The new regulator operates on pilot channels rather than on a pilot-wire. Currents of single-frequency are transmitted over a pair of conductors, the gain being regulated in accordance with the attenuation changes of these pilot channels. Regulation is thus directly associated with the carrier system operating on that pair. The change in gain is the same at all frequencies. Regulation as designed is used not only to compensate for the residual regulation errors of a 300–500 mile circuit, but also to take care of the flat regulation of the previous repeater section (12–20 miles) and also the slope and bulge regulation of the previous twist section (50–300 miles), obviating the necessity for pilot-wire and twist regulators. Measurements over a four-monthly period, using continuous recorders, showed that variations in the net losses of the twelve channels due to changes in line loss were not more than 0·5 db., an improvement of more than two to one as compared to the performance previously available without the deviation regulator.

Overheating of Electric Motors

AN article on this subject in the *Electrical Review* of July 31 opens with a brief survey of overheating due to dirt or other foreign matter obstructing the ventilating pipes, ducts and passages of motors. Mention is made of the lagging effect which waste materials may have on the motor casing, and useful suggestions are given for the improvement and maintenance of ventilation. Since the rate of heat generation is proportional to the square of the load, protection against overloading is advised. It is suggested that motors be protected by a tripping device operating at 25 per cent sustained overload, or thermostatically controlled if subjected to large rapid load fluctuations. The liability of cotton insulation to char at about 100° C. is mentioned in stressing the safe temperature rise of a winding as being about 72° C. above that of the surrounding atmosphere.

The author then outlines the effects of accidentally sustained starting currents, mentioning in this connexion the mal-operation of star-delta starters. Warnings are given against running D.C. variable-speed motors at abnormal speeds; series connecting the windings of small A.C. motors intended for use on two voltages when on full load; prolonged connexions of the starting windings of split-phase single-phase motors; and the running of polyphase motors with one phase of the supply open-circuited. The remainder of the article is devoted to interesting points in maintenance, attention being directed to worn bearings, lubrication, short-circuited windings, short-circuiting of commutators by carbon dust, and the careless handling of dismantled machines as possible causes of overheating. Attention to the many points referred to will doubtless minimize the risk of overheating, rapid deterioration and breakdown of the plant.

Rats and the War

ACCORDING to the *Medical Officer* of August 15, Dr. Charles White, medical officer of health for the City of London, has recently issued a report to the effect that while the devastation caused by enemy action has undoubtedly reduced the rat population, particularly in the Cripplegate area, in other districts there is still severe infestation by these vermin. Premises previously more or less free now suffer constant infestation, especially buildings in which the upper floors only were damaged by fire or blast. The hundreds of sandbag blast walls have formed a safe harbour for rats, but many have now been replaced by brick structures. Infestation by rats has been aggravated by the introduction of fire-guarding and consequent indiscriminate feeding, as well as by leaving doors open throughout the buildings to facilitate fire-guards access to rooms. Dr. White recommends that when structural reconstruction is considered adequate steps should be taken to construct rat-free buildings.

The National Trust

IT is satisfactory to learn from the forty-seventh annual report of the National Trust for Places of Historic Interest or Natural Beauty that progress is being made in spite of the War. The recent outstanding addition to the Trust's properties is the Wallington estate in Northumberland, but while this is the largest (13,000 acres) there are many other interesting and beautiful places now saved for the nation in no less than twelve counties. The report, which is also concerned with problems of future upkeep, preservations of buildings and amenities, and of the plant, fish and even bird life of Ullswater, can be obtained at 7 Buckingham Palace Gardens, Westminster, and is a cheering document to turn to in this time of strife and destruction.

Post-war Medical Relief

In a timely pamphlet (Post-War Problems Medical Relief in Europe. The Royal Institute of International Affairs, 1942. Pp. 67. 2*s*. net.), Dr. M. D. Mackenzie emphasizes the importance of organizing before the end of the War a central co-ordinating administrative machine composed at first of delegates of the allied countries and later of representatives of occupied countries as well. He suggests that the Health Organisation of the League of Nations, which still functions, should be used and should be joined by international voluntary organizations (International Red Cross, Society of Friends, etc.), British and American voluntary organizations for relief in Europe and the national voluntary organization in each of the countries to which relief is being given. In addition to food and clothing, medical relief material of all kinds will be wanted, including vaccine against smallpox and enteric fever, disinfectants, quinine and other important drugs, as well as re-establishment of the milk supply. The specific diseases which will need attention are malnutrition including tuberculosis, typhus fever, malaria and other infectious diseases as well as cardiac and digestive disorders.

Smallpox in the United States

According to an annotation in the June issue of the *Statistical Bulletin*, the organ of the Metropolitan Life Assurance Company of New York, a remarkably low record for smallpox was established for 1941 in the United States, only 1,432 cases having been reported in the whole country during that year, or scarcely more than half the number notified in 1940 (2,795). In Canada also the incidence of smallpox was very low, only 26 cases having been reported, all but one of which occurred in the single province of Saskatchewan. As in previous years, the type of the disease in the United States was mild, and it is probable that not more than ten deaths occurred. There is good reason to believe that the present decline is real, and that the disease will be eradicated in the next decade. During the past twenty-one years, nearly half a million cases of smallpox have been reported in the United States, one State alone, Indiana, being represented by 37,902 cases. The chief centre of smallpox infection in the United States recently has been in the north-west corner of the country which comprises the States of Montana, Washington, Idaho and Oregon, while the lowest incidence is in the New England and Middle Atlantic States, followed by the States in the south-east corner of the country. The high incidence in Indiana is to be attributed to the fact that at a recent survey less than 13 per cent of the Indiana pre-school children and not more than 53 per cent of school children less than ten years of age were found to be vaccinated. It is therefore highly desirable that the following warnings should be widely spread: (1) no one is naturally immune to smallpox; (2) protection against it must be acquired artificially by vaccination; (3) the immunity conferred by vaccination is not life long, but must be renewed by revaccination at intervals of seven years or when an outbreak of smallpox occurs.

Recent Earthquakes

On August 24 an earthquake of considerable intensity caused destruction in places 50 miles apart in southern Peru. The epicentre of the shock was probably a little distance to the north-west of Acari, which is a town in the foothills of the Andes in the province of Arequipa. The town of Acari was almost destroyed and there are reported to be large numbers of dead and injured. At Nazca, a town some 50 miles north-west of Acari, one third of the buildings were completely destroyed and 80 per cent of the population are homeless. Here 20 people are reported to have been killed and several injured. At the coast near the port of Nazca the sea receded some 200 yards and then came back and flooded the port together with about 1,000 yd. of the Pan-American coastal highway. The shock was well recorded at Stonyhurst College Observatory, near Blackburn; the Rev. J. P. Rowland, *S.J.*, reads eP_E at 23h. 03m. 37s. U.T. on August 24, the maximum ground amplitude at Stonyhurst being 600 μ at 39m. 40s. U.T. The shock finished recording at 04h. 10m. U.T. on August 25, all the interpretations being tentative.

The seismograph at Stonyhurst also recorded another earthquake, this time on August 27 at 06h. 18m. 40s. U.T. The record was well defined, but the amplitudes were much smaller than those of the Peruvian shock, and the epicentral distance from Stonyhurst much less. The German radio has reported an earthquake in Albania. In one village 80 per cent of the buildings are said to be uninhabitable, and many people killed and injured.

Announcements

Sir John Orr, director of the Rowett Research Institute, Aberdeen, has been appointed professor of agriculture in the University of Aberdeen. He will retain the directorship of the Institute.

The Minister of Agriculture and Fisheries has appointed Mr. F. A. Secrett to be honorary adviser on vegetable production. Mr. Secrett is the head of Messrs. F. A. Secrett and Co., the well-known firm of vegetable growers. His wide experience and intimate knowledge of the industry will be invaluable to the Ministry in the work of increasing the production of home-grown vegetables.

The next meeting of the Parliamentary and Scientific Committee to be held in Room 6 of the House of Commons, at 2.45 p.m. on September 8, will consider, among other things: "further action to be taken on the Motion now on the Order Papers of the House with a view to the setting up of a central Technical and Scientific Board; to consider representations from a representative from the Geological Society with regard to the better use of geology in connexion with the war effort."

Following the conference held at the Institution of Civil Engineers on August 25 to discuss generally the question of civil engineering and the building industry, discussion meetings will be held at four-weekly intervals beginning September 15 at 2.30 p.m., to consider the specific problems that emerge. Mr. George Hicks, Parliamentary Secretary to the Ministry of Works and Planning, will be the principal speaker at the first meeting. Particulars and tickets for a particular meeting or for the series may be obtained on application to the secretary of the Institution of Civil Engineers, Great George Street, Westminster.

Antipressor and Depressor Effects of Oxidation Products of Pressor Amines

PRESSOR amines comprise a great variety of β-substituted primary and secondary alkylamines the cyclic portion of which may contain one or two phenol groups. The various functional groups determine the catabolic fate of these amines which, in turn, contribute to the nature, intensity and duration of their action. Because of the role attributed to pressor amines in essential[1] and in experimental[2] hypertension, the mechanism of their inactivation and destruction is of pathological and pharmacological interest.

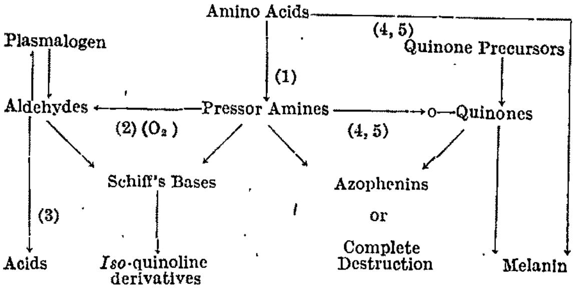
(*a*) Oxidative mechanisms can attack either the side chain or the cyclic portion of the pressor amine molecule. Oxidation of the latter leads from, or through, catechol derivatives to *ortho*-quinones and eventually to melanins. The formation of *o*-diphenolic compounds by enzymatic or other chemical and by physical means in the animal body from monophenols is still obscure[3,4]. The *ortho*-quinones, known as intermediaries in melanin formation[5], may also undergo azophenine-like condensations with additional amine molecules. Thus, the destruction and physiological inactivation of additional molecules of pressor amines is accomplished.

Schroeder and Adams[6] lowered the blood pressure in experimental hypertension by injection of mushroom tyrosinase. This effect is attributable either to complete enzymatic oxidation of the phenolic pressor amines or to their inactivation by the *ortho*-quinoid intermediaries formed in the course of tyrosinase action. The latter alternative is supported by the lowering of blood pressure in experimentally hypertensive rats and dogs after injections of the quinone precursor dihydroxyphenylalanine together with small amounts of copper salts as oxidation catalyst[7]; analogous *in vitro* experiments demonstrate that pressor amines (tested in crucial experiments on cats) are destroyed by aeration with quinone precursors and also with aliphatic enediols in the presence of heavy metal catalysts[7]. Adrenochrom, a cyclized *ortho*-quinone derived from adrenaline, is also known as a hydrogen acceptor in vital oxidation processes[8] and its 'trigger action' upon certain effects of adrenaline illustrates the physiological operation of a catechol-*ortho*-quinone system. Preliminary experiments[9] with injection of relatively stable halogenated adrenochrom derivatives show an antipressor effect in experimentally hypertensive rats and dogs.

(*b*) Kisch[10] has shown that the aeration of solutions of amino acids and dipeptides in the presence of adrenaline and other quinone precursors such as hydroxyquinol results in oxidative deamination. Beyer[11] obtained analogous results with ascorbic acid, an aliphatic diketone precursor. Thus, in Kisch's experimental model an intermediary product of nuclear oxidation catalyses in its turn a side chain oxidation.

(*c*) Enzymatic oxidation of the side chain of pressor amines is accomplished by amine oxidase found in kidney, liver, brain and other organs. This enzyme was discovered by Hare[12] who demonstrated its effects on tyramine *in vitro*. The products of oxidative deamination are ammonia and the corresponding aldehydes, in the case of tyramine, *p*-hydroxyphenylacetaldehyde. The aldehydes formed by the action of this enzyme are subject to further oxidation by the hepatic xanthine oxidase to the corresponding acids, which have so far not been found to be of physiological significance. This, however, is not the only reaction which these aldehydes may undergo. Mrs. M. Hare Bernheim[13] discussed the potential condensation of one molecule aldehyde with another molecule of unchanged amine to a Schiff's base. Again, as in the case of the *ortho*-quinoid primary destruction products, the formation of the aldehydes does not mean only the removal of one molecule of pressor amine, but produces an additional antipressor effect by condensation of the aldehyde with a second molecule of amine to a physiologically inert compound. These Schiff's bases are, in turn, subject to cyclization yielding *iso*-quinoline derivatives along the line of the papaverine synthesis of Robinson[14]. These *iso*-quinoline derivatives are related to the fast-acting alkaloids of the papaverine and laudanosine group. Their formation could explain the depressor effect of homoprotocatechuic aldehyde, the deamination product of hydroxytryamine, observed by Holtz[15]. A similar chemical transformation of adrenaline into a substance of antagonistic properties may account for the so-called diphasic action of adrenaline injections[16]. Especially the infusion of minute amounts accentuates this antagonistic action as the rate of transformation exceeds the rate of direct action.

The subjoined diagram shows that the various possible oxidation products of pressor amines may have: (1) an antipressor effect by inactivating additional amounts of pressor amine; (2) a depressor effect as in the case of *iso*-quinoline derivatives and perhaps their aldehydic parent substances; (3) the final oxidation products such as melanin and aromatic acids are indifferent, and there is finally (4) the possibility of storing a physiologically active intermediary in a temporarily inert state.



(1) Decarboxylase (aerobic and anaerobic).
(2) Amine oxidase (aerobic), also with creso-indophenol as H-acceptor[22].
(3) Xanthin oxidase.
(4) Monophenolase and (5) catecholase.

Aldehydes are known as rather reactive substances unlikely to persist in living tissue. Certain aliphatic aldehydes, however, have been found by Feulgen[17] in lipoid extracts of muscle, blood and viscera bound by cyclic acetal linkages in the so-called plasmalogen. This acetal phosphatid upon hydrolysis liberates plasmal, a mixture of aldehydes, including stearic and palmitic aldehyde. The presence of aldehydes other than these saturated higher aldehydes has been suspected by Feulgen[18]. Attempts in collaboration with H. Sobotka to isolate aldehydes from hog kidney have resulted in the identification of stearic aldehyde[19], but also indicate the presence of mixed aromatic-aliphatic aldehydes. An interchange may exist between these two classes of aldehydes and they may replace each other in acetal phosphatides. Striking differences in the occurrence and distribution of bound aldehyde in normal and pathological kidneys from human autopsies speak for the physiological significance of stored aldehyde[19]. Thus, aldehydes with antipressor and depressor effect may be conserved in this form, so that they may be mobilized for various needs of the organism. These aldehyde depots can be depleted in tissue sections by incubation with aromatic amines such as sulphanilic and *para*-aminobenzoic acids and may serve a similar purpose of local detoxification *in vivo*. They would be especially suitable to combat undesirable accumulations of pressor amines. Thus they may function as temporary 'buffers' delaying the onset of experimental hypertension which, in spite of the immediate production of renal ischemia, appears only three or four days after the Goldblatt operation.

The above diagram illustrates the hypothetical sequences of reactions from cyclic amino acids through pressor amines, antipressor and depressor substances to inert end-products. The equilibrium between these transformations, obtaining under physiological conditions, is disturbed in renal hypertension; the pressor amines then accumulate and at the same time their antagonists are depleted and used up. Extracts with depressor effect have been obtained from normal kidney[20]. In experimental unilateral renal ischemia in dogs[21] the production of the antagonists in the intact kidney prevents the persistence of hypertension in spite of the continuous output of pressor amines from the ischemic kidney.

Self-incompatibility in Certain Diploid Potato Species

PAL and Puskar Nath[1] have reported that the diploid ($2n = 24$) potato species, *S. arrac-papa*, *S. Caldasii*, *S. chacoense*, *S. Jamesii* and *S. subtilius*, are self-incompatible. Under Cambridge conditions the diploid species, *S. Rybinii*, *S. boyacense*, *S. lanciforme* and *S. phureja*, also appear to be self-incompatible.

Only one clone of *S. Rybinii*, which Salaman[2] states he was unable to infect with either leaf roll or potato virus *Y*, has been brought to Europe, and on selfing this clone never sets berries. It will, however, cross readily with the closely related species *S. boyacense* (clone *E.P.C.* 546), which also does not set berries on selfing. Berries containing a very large number of seeds are obtained from this cross and from the reciprocal. Also, as is shown in the table, F_1 plants from the cross are cross-compatible with either parent. It has not, however, been possible to show that only four types of F_1 plants, such as would be expected on a simple oppositional factor hypothesis, are produced.

	FEMALE PARENT					
MALE PARENT	*S. Rybinii*	*E.P.C.* 546	$F_1$4	$F_1$6	$F_1$8	$F_1$10
S. Rybinii	−	+	+	−	+	+
E.P.C. 546	+	−				
$F_1$4	+		−		−	
$F_1$6			+		−	+
$F_1$8	+	+	−	−	−	+
$F_1$10	+	+		−	+	−

+ = compatible pollination; − = incompatible pollination; $F_1$4, 6, 8, and 10 = F_1 (*S. Rybinii* × *E.P.C.* 546).

No berries have been obtained from selfing any of the clones of the blight-immune, Mexican diploid species *S. lanciforme* which was brought back by the Empire Potato Expedition as seeds. Berries containing numerous seeds have, however, been obtained from the following crosses between clones, *E.P.C.* 40·3 × 40·4, *E.P.C.* 40·3 × 40·7, *E.P.C.* 40·4 × 40·3, *E.P.C.* 40·6 × 40·3 and *E.P.C.* 40·6 × 40·4.

Similarly, two clones of *S. phureja*, *E.P.C.* 1307 and *E.P.C.* 1310, have never set berries on selfing, but berries with seeds were obtained from the cross *E.P.C.* 1310 female × *E.P.C.* 1307.

Effect of Sulphanilamides on the Growth of Micro-organisms in Presence and Absence of *p*-Aminobenzoic Acid

LAST year I presented some results of experiments on the antagonism between *p*-aminobenzoic acid and sulphanilamides (sulphanilamide, sulphapyridine and sulphathiazole) in autotrophic organisms[1]. These experiments were carried out with two strains of the freshwater diatom *Nitzschia palea* var. *debilis* (Kg.) Grun. I also made experiments on the inhibitory action of sulphanilamide on the growth of *N. communis* Rabenhorst, *N. Kützingiana* var. *exilis* Grun. (f. *multiplex*[2]) and further strains of *N. palea* var. *debilis*.

The growth of the diatoms, which were cultured on a substrate used by me[2] earlier[3] and known to be free from anti-sulphanilamide factors, was more inhibited by sulphanilamide than by sulphapyridine, which in turn had a somewhat stronger effect than sulphathiazole. In other words, the action of the sulphanilamides mentioned on the growth of the diatoms was the reverse of that on bacteria.

The antagonistic power of *p*-aminobenzoic acid on sulphanilamides in these experiments with diatoms was, however, similar to that in corresponding experiments with bacteria, the inhibitory activity being strongest against sulphanilamide, less strong against sulphapyridine and least against sulphathiazole. Although *p*-aminobenzoic acid probably is an essential metabolite (in the sense of Fildes[4]) for diatoms as well as for bacteria and fungi, the conditions—at least for the diatoms investigated—seemed to be more complicated, and it was assumed that the pyridine and thiazole groups of sulphapyridine and sulphathiazole made these influence also vital processes in the metabolism of the cell other than those connected with the *p*-aminobenzoic acid (cf. the opinion of West and Coburn[5] concerning the competition of sulphapyridine with nicotinic acid in the formation of coenzymes).

A connexion between my experiences with diatoms and the results from the investigations on bacteria was seen when Landy and Dicken[6] reported their experiments on the neutralization of sulphanilamides through *p*-aminobenzoic acid in yeast. Their growth diagram shows a crossing between the sulphanilamide and sulphapyridine curves, indicating that at certain higher concentrations of *p*-aminobenzoic acid the growth of yeast is less inhibited by sulphanilamide than by sulphapyridine, whereas at lower concentrations the reverse is true. This probably explains my own experiences with diatoms, although the response to sulphathiazole does not seem to be identical in the two groups of organisms.

Rapid Determination of Fat in Animals and Plants

The living organism or tissue is weighed, preferably by the displacement method[1], and placed in a weighed Soxhlet thimble. It is then distilled under xylol, and the percentage of water estimated[2]. Any fat will remain in the xylol. A further extraction is carried out with xylol in the ordinary Soxhlet extractor and then the whole of the xylol used is made up to a litre or some other standard volume. Then 200 ml. of this xylol is placed in a round-bottomed flask together with about 200 ml. of distilled water and steam-distilled.

The vapour pressure of the xylol being well above that of steam and that of the fat being well below, the fat remains in the flask and the xylol is carried over. The water and fat from the flask are washed out into a separating funnel while still warm and allowed to cool. A small amount of hydrochloric acid is added to bring about demulsification and the whole is shaken up vigorously with petroleum ether. The fat dissolves and is estimated in the ordinary way by evaporating off the petroleum ether.

The method has been tested out thoroughly with lard and pure olive oil. It is obviously limited in its application but has the great advantage that it is unnecessary to dry the material containing the fat.

If a little of the original material is first steam distilled it will be seen at once if it contains volatile oils or fats and if it does the method is clearly unsuitable.

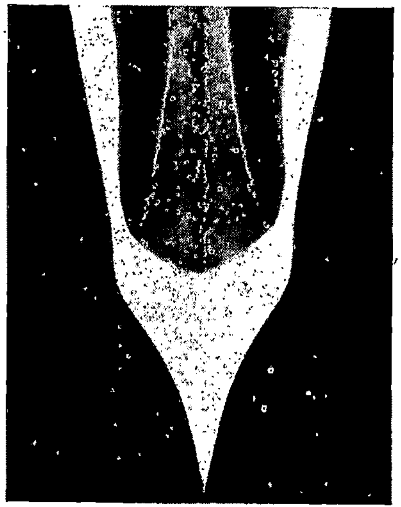
Luminous Radiation from Hot Gases

The question as to whether normal gases become luminous when heated is of the greatest importance to those interested in the physics and chemistry of flame gases. Pringsheim did a great deal of work with the view of deciding this, and found that they remained dark at the highest temperature he could command in the laboratory[1]. In recent books by Lewis and von Elbe[2] and Gaydon[3], however, doubt is expressed whether at temperatures of the order of 2,000° C. they would still remain dark.



I think there is no doubt that they would. Weston's spectrograms from carbon monoxide – air flame gases and the higher temperature carbon monoxide – oxygen flame gases show that when hydrogen is added, the characteristic carbon monoxide flame gas spectrum disappears—even though the flame gas temperature is higher[4]. The explanation would appear to be that, with addition of hydrogen, the carbon dioxide produced is much more normal, for it has been shown that the latent energy in carbon monoxide flame gases decreases with addition of hydrogen. (Gaydon suggests that the luminous radiation from carbon monoxide flame gases results from continual recombination after dissociation of the carbon dioxide. Weston's experiments do not appear to support this view, for a large amount of dissociation and recombination must be taking place in the high temperature carbon monoxide – hydrogen – oxygen flame gases.)

A further indication that hot normal carbon dioxide does not emit luminous radiation may be derived from flame photographs, which show remarkable variations in the intensity of the after-glow in carbon monoxide flame gases resulting from explosions in a glass tube. One such photograph taken by Dr. A. S. Leah is reproduced herewith. His experiments have shown that the temperature of the gases showing almost negligible after-glow is higher than that of the gases in the immediate neighbourhood which show a strong after-glow. There can be little doubt that the carbon dioxide in the former gases is much more normal than the carbon dioxide in the latter gases[5].

Diffraction of Ultra-Short Radio Waves

WE have pointed out[1] that ultra-short radio waves polarized with the electric vector vertical are propagated into the shadow of hills more readily than horizontally polarized waves. We have since observed the opposite effect for receiver positions beyond hills but just outside their shadow. Fig. 1 represents roughly the terrain over which these results, shown in the table, were obtained. The transmitter *T* was near the top of one ridge and the field strength investigated over the region *ABCD*; horizontally and vertically polarized radiation was emitted in turn from the transmitter on a wave-length of 3 metres, and the aerial at the receiver oriented to correspond for each measurement with the appropriate transmitter polarization. Over the region *ABC* within the geometrical shadow of the ridge having a crest at *A*, the vertical electric field, in agreement with our earlier note, was greater than the horizontal field, the ratio of these two fields, as will be seen from the table, being unity near the edge of the shadow at *A* and *C* and a maximum near the bottom of the valley at *B*. Just outside, however, the horizontal field was greater than the vertical, the ratio showing a flat maximum.

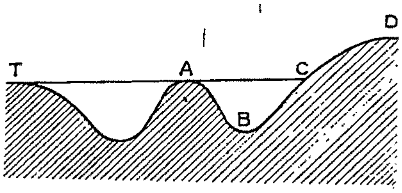

Fig. 1.

These experimental results are similar to those found both theoretically[2] and experimentally[3] in the diffraction by a straight edge or wedge of radiation in the visible spectrum. As the radius of the curvature of the ridge in our experiments was large compared with the wave-length, similar results would be obtained if the obstruction caused by the ridge is assumed to represent that due to the earth's curvature. It may be concluded, therefore, that for an elevated transmitter *T* (Fig. 2) and receiver positions within the shadow *ABC* cast by the earth's curvature, vertical polarization should be used, but for positions just outside that shadow, horizontal polarization is more efficient. Horizontal polarization may, in practice, be the better for transmitter and receiver positions such as *T* and *R* (Fig. 2) well within optical range of one another if *R* is at such a height as to be just outside the shadow caused by the continuous diffraction due to undulation of the ground, houses, etc. In addition, horizontally polarized radiation may be better over tree-clad country, under the above conditions, on account of the materially greater attenuation caused by trees to vertically polarized radiation at ultra-short wave-lengths.

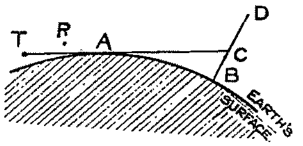

Fig. 2.

Position	Field-strength in microvolts per metre		Ratio Vertical/ Horizontal fields	Remarks	
	Vertical polarization	Horizontal polarization			
1	32,000	31,000	1·03	Position *A*	in shadow
2	6,300	4,100	1·54		
3	2,500	950	2·63		
4	1,200	500	2·40		
5	1,080	530	2·04	Position *B*	
6	1,900	1,400	1·36		
7	7,900	8,400	0·94	Position *C*	outside shadow
8	9,800	11,500	0·85		
9	12,000	19,700	0·61		
10	9,800	17,500	0·56		
11	6,500	9,800	0·66		
12	2,000	2,220	0·90		
13	740	710	1·04	Position *D*	

The work described above was carried out as part of the programme of the Radio Research Board, to which this note was first circulated as a confidential report, on March 11, 1940. It is now published by permission of the Department of Scientific and Industrial Research.

Frequency of Dust-storms in the Egyptian Desert

WHEN I reviewed[1] the book by Lieut.-Colonel R. A. Bagnold on the "Physics of Desert Sands and Dunes", I noted a statement by the author that dust-storms, as distinct from sand-storms, were of comparatively rare occurrence in the Egyptian desert, whereas dust-storms were being reported in the news as interfering with the fighting in the Middle East every few days. At the time, I regarded the term 'dust-storm' as being somewhat loosely applied by the reporters, and to include sand-storms, but I have recently had the opportunity of reading a paper[2] by Prof. F. W. Oliver which throws new light on this point. Prof. Oliver has lived since 1935 at Burg-el-Arab, thirty miles west of Alexandria, and he states that changes have occurred in recent times. The average dust-storm frequency from 1935 to 1939 was 5 a year over the period January to May; in the same period of 1940 there were 8, and in 1941 there were 32 storms. The total number for the year 1941 was 54, and in addition to the increased frequency, the severity was much greater.

Prof. Oliver accounts for this increased frequency first by the surface disturbance caused by war operations in the desert, such as construction of fortifications and movement of lorries; and secondly, by the removal of cover, that is, desert scrub, which was destroyed by the Bedouins when they evacuated from the district. He considers that extensive measures will need to be taken after the War to abolish the dust nuisance in these districts.

Social Reporting

IN the review of Mass-Observation's recent report "People in Production"[1], the main theme of this report seems to have escaped the reviewer's attention.

What "People in Production", a report on six months study in war factories, analyses out is a fundamental psychological tendency of our present civilization, seldom realized or studied—the 'quantitative approach'. The idea that you are doing well by producing a lot of things, by having so many tanks brought off the production lines every day; so many Flying Fortresses flown across the Atlantic every week; such and such an enormous percentage of men conscripted into the Forces, and of women directed into industry; long hours of work; impressive figures of war money expenditure—these have been the common encouragements of Lord Beaverbrook, Mr. Lyttelton, Mr. Bevin and others. Our production study attempted to show how this heavily quantitative approach has led to a neglect of qualitative considerations. These qualitative considerations are of two main types—the quality of the materials produced, and the quality of the personnel dealing with the product. The former type lies outside the realm of sociology, but no one who has read *Hansard* on the two days of the recent Censure Debate, including Mr. Lyttelton's speech, can doubt that there has been some muddled thinking on this side. We were concerned with the latter type.

We found over and over again that the qualitative, social and psychological factors were being ignored. The underlying assumption in war industry and in the Services, all the way through, is that men and women are units of subsidiary importance to machines, yet with many mechanical attributes. The qualitative human factors, which distinguish a soldier from a rifle, a working girl from a capstan lathe, are ignored to a surprising extent. This leads to many avoidable inadequacies. To put it in its simplest form: it does not matter how many tanks you have in Libya, or even how good they are, if the people handling them are not fully tank-minded, tank-educated, and tank-determined. Lots and lots of everything will not win anything. It is the human element, both in producing and in *using* the products which will determine the outcome of the War. This elementary point has been astonishingly ignored. It is not so astonishing, however, if it is related to the growth of industry, with its economic and numerical incentives, and this, too, we have tried to trace out in "The People in Production". The statistical obsession of the social sciences has also contributed to a neglect of the real, *human* factors.

Such material is certainly topical, and as such might, I suppose, be called 'social reporting'. But even the social sciences cannot stand above the battle. With complacency, the reviewer concludes that our study shows how "countless relatively small mistakes are being made everywhere, an ordinary state of human affairs". We cannot, at present, afford to be ordinary. The "countless relatively small mistakes" are related to a central theme, which requires analysis. What a negation of sociology to dismiss it as merely an ordinary human state: what is social science about if not that? I for one am happy to be called superficial if in being so I am helping to illuminate the mentality of the present and to preserve the integrity of the future, however inadequately.

TOM HARRISSON.

Mass Observation,
82, Ladbroke Road,
London, W.11.

---

[1] NATURE, 149, 711 (1942).

THE review to which Mr. Harrisson objects made it abundantly clear that the report was concerned with "the quality of the personnel dealing with the product". Ten topics of the report were mentioned, all of which dealt with qualitative, social and psychological factors. The comment was made "Emerging from the survey of most of these problems is the evident need for everybody to understand more fully what other people are doing and the conditions of their work. The Fighting Services, the Supply Ministries, management, foremen and workers all need to know more about each other. Extensive reporting of the kind offered here is one means of fulfilling the need."

What Mr. Harrisson misunderstood as my complacency about the "ordinary state of human affairs" might better have been called pessimism, except that I believe it to apply to the state of enemy affairs as well as our own. To say that the small mistakes are related to a central theme is either a truism (since everything which happens in a social group is related to some vague central theme), or else it implies a dubious political or sociological dogma, as I supposed from Mr. Harrisson's remark, "*Something* is seriously wrong somewhere". THE REVIEWER.

RESEARCH ITEMS

Lipoid Compounds in Physiological Processes

THE importance of lipoid compounds in physiological processes such as blood clotting, in which prothrombin is activated by thrombokinase, a kephalin protein complex, or in immunological reactions where lipoid 'haptens' are assumed to join up with protein in the blood to form true antigens, is being increasingly realized. The Food Investigation Board of the Department of Scientific and Industrial Research has just issued Food Investigation Report No. 52—"The Mode of Occurrence of Fatty Acid Derivatives in Living Tissues"—by J. A. Lovern, Torry Research Station (H.M. Stationery Office. Pp. 36). This deals with the types of fatty acid derivatives occurring in lipoidal extracts, with the dynamic state of lipoids in the tissues and mainly with the lipoid-protein and lipoid-carbohydrate complexes of animals and plants. The available evidence concerning these complexes is considered according to the experimental methods used—physical methods (histological, physical determinations), physiological studies (blood clotting, antigenic reactions), solvent extraction of tissues (animal tissues, vegetable tissues), experimental preparation of lipoid-containing complexes, isolation of natural lipoid complexes, lipoprotein 'gliodes'. Comment is made on methods of splitting certain lipoproteins which may have a more general application in displacing acidic prosthetic groups from protein carriers. By adding a highly basic protein such as salmine, the phosphatide is detached, forming a phosphatide-salmine complex and leaving the original protein free and undenatured. Conversely, the addition of heparin with the formation of a heparin protein complex leaves the lipoid free. There is evidence of more than one type of lipoid-protein and lipoid-carbohydrate linkage, ranging from mere adsorption to complexes to definite chemical compounds which can be split only by drastic chemical action. An example of the latter is a lipoprotein from horse serum which is completely soluble in water, contains 22·7 per cent phosphatides, 17·9 per cent cholesterol esters and 59·1 per cent of a protein having the properties of an albumin. In spite of this high lipoid content, ether only extracts mere traces of lipoids from its aqueous solutions.

Bean and Dock Aphides

UNDER the title of "A Description of *Aphis (Doralis) rumicis* L. and comparison with *Aphis (Doralis) fabæ* Scop." Margaret E. Jones contributes the results of investigations on these two species to the April issue of the *Bulletin of Entomological Research*, 33, 1 (1942). Both species are black in colour and both occur on species of dock (Rumex), with the result that much confusion prevails regarding their identity. *Aphis rumicis*, it is pointed out, is monophagous and confined to that host plant, while *A. fabæ* is polyphagous and is the well-known 'black fly' that infests the broad bean. *A. rumicis* is non-migratory whereas *A fabæ* over-winters on other plant-hosts, namely, Euonymus and *Viburnum Opulus*. The sexuales individuals in the two species are very distinct, the males of *rumicis* being apterous and those of *fabæ* are winged. In the case of the oviparous females those of *fabæ* have broad hind tibiæ plentifully endowed with sensoria. whereas the oviparous forms of *rumicis* have slender hind tibiæ bearing very few sensoria. Differences between the two species regarding the viviparous forms are also described and the paper contains a number of explanatory text-figures.

Plant Oils as Insecticides

A TECHNICAL BULLETIN, No. 801, February, 1942, has been issued by the United States Department of Agriculture (Washington, D.C.), entitled "Insecticidal Efficiency of some Oils of Plant Origin", by A. W. Cressman and Lynn H. Dawsey. Oils may be classified into three groups according to origin—plant, animal and mineral. Oils of the last type, especially petroleum oils, have found wide utility in insect control, most of the American investigations being based on this class. The trouble with these oils has been the injurious effects which may be produced on the plants to be protected. For foliage sprays, plant oils would reduce this danger. The authors compared the insecticidal efficiencies of a number of oils of plant origin with that of a refined petroleum oil. Emulsions were prepared by mixing these oils with ground bone glue in a high-speed drink mixer. Tests, for which the Bulletin must be consulted, were carried out on Mexican mealy bugs reared on potted chrysanthemum plants in the greenhouse, which were sprayed in the laboratory. Mature females and eggs of the willow scurfy scale on willow twigs and fruit-tree leaf roller eggs on apple twigs were collected in the field and brought to the laboratory for treatment. Oils experimented with were crude corn oil, crude cottonseed and pea-nut oils and their refined stages, also orange and pine oils. It is stated that "Although vegetable oils are generally higher priced than petroleum oils, they possess superior solvent action for certain organic insecticides, and may find new uses because of this property".

Insects and Azalea Flower Spot

A TECHNICAL BULLETIN, No. 798, January, 1942, entitled "Relationship of Insects to the Spread of Azalea Flower Spot", by F. F. Smith and F. Weiss, has been issued by the U.S. Department of Agriculture (Washington, D.C.). The investigations were carried out between 1934 and 1938. It was found that five species of bumble bees (Bombus spp.), two species of carpenter bees (Xylocopa spp.), *Emphoropsis floridana*, and the honey bee, *Apis mellifera*, are the most conspicuous visitors, although thrips, flies and many others come to the flower. It is concluded that, while insects are at times efficient vectors of the organism, they are not primarily responsible for the development of the disease when once it has become established in a given planting. They may, however, be concerned with its spread to nearby plantings of azaleas. Controlling the disease, rather than the insects, therefore appears to be the logical means of attacking the problem, a method which has to be attempted so often by the forester as well as the horticulturist.

Plant Diseases in Scotland

R. W. G. Dennis and C. E. Foister publish a long list of plant diseases found in Scotland (*Trans. Mycol. Soc.*, 25, Pt. 3; June, 1942). An important feature of the paper is the demonstration that several plant parasites common in England are not abundant north of the border. Downy mildews are scarce, except those caused by *Peronospora parasitica* and *Phytophthora infestans*. Rots due to *Sclerotinia sclerotiorum* are seldom encountered; white root rot, *Rosellinia necatrix*, has not been reported, and violet root rot, *Helicobasidium purpureum*, is rare. Such common English cereal maladies as *Puccinia triticina*, *Ophiobolus graminis* and *Septoria Tritici* are either unknown or are seldom discovered. Scotland has the doubtful distinction of having been the channel of introduction of *Puccinia mirabilissima* on *Mahonia aquifolia* to other parts of the British Isles, but there appear to be very few diseases which are widespread in Scotland and absent from England—a fact of undoubted importance in the ecology of fungi.

Bacterial Canker of the Peach

A SHORT paper by H. Wormald (*Trans. Brit. Mycol. Soc.*, 25, Pt. 3; June, 1942) describes a bacterial canker of the peach caused by *Pseudomonas mors-prunorum*. The disease kills infected branches and discolours the cortex. Pathogenicity has been established by inoculation, but the malady is fortunately not very widespread at present.

Genetics of Mating in Euplotes

R. F. KIMBALL (*Genetics*, 27, 269; 1942) has discovered a multiple allelomorph series which controls conjugation in *Euplotes partella*. Six lines (or types) descended from two individuals will not generally mate within themselves but will mate with each other. An allelomorph series controls each mating in such a way that individuals carrying similar genes of this series do not conjugate. Types III, IV and VI are homozygous for the three members of the multiple allelomorph series, and types I, II and V are heterozygotes. It was found that animal-free fluid from one mating type may induce matings of animals of different type. Further investigation shows that fluid from a heterozygous type induces mating in the remaining five types, but from a homozygous type induction of mating only occurs in those types which do not have an allelomorph in common. There are aberrations in the data, such as unexpected matings within a type and failure of conjugation where it is expected; but the general scheme is coherent and further work is proceeding to analyse the exceptions. It is noteworthy that the allelomorphs produced qualitatively different substances which induce mating, and that in the heterozygote the allelomorphs are independent and not conjoint in action.

Crystal Structure of Cobalt

THE X-ray photographs obtained from cobalt depend markedly upon the previous history of the particular specimens used. The same powder photograph may include face-centred-cubic and close-packed-hexagonal lines. While this two-phase state has generally been ascribed to the presence of impurities, O. S. Edwards and H. Lipson have obtained similar photographs from cobalt of 99·99 per cent purity (*Proc. Roy. Soc.*, A, 180, 268; 1942). The photographs show a remarkable mixture of sharp and diffuse lines. The sharp lines have $\frac{1}{3}(h-k)$ integral or l zero. All others are more or less diffuse. An explanation of this is produced, based on the possibility of 'faults' occurring in the structure, because there are two different ways in which one close-packed layer of atoms can be fitted on to another. It is shown theoretically that if such faults are repeated at regular intervals the reflexions with $\frac{1}{3}(h-k)$ integral are not affected, but the positions and intensities of the other lines are modified although they remain sharp. A structure with random faults would give on powder photograph broadened reflexions except for lines with l zero. A mathematical treatment of the proposed structure is given by A. J. C. Wison (*loc. cit.*, p. 277). The frequency of faults in the specimen used in the experiments is found to be, on the average, about one in every ten planes.

Free Radical Chain Reaction

A STUDY of the detection and inhibition of free radical chain reactions has been made by J. R. E. Smith and C. N. Hinshelwood (*Proc. Roy. Soc.*, A, 180, 237; 1942), comparing nitric oxide and propylene as inhibitors. Inhibition curves for the thermal decomposition of diethyl ether in the presence of propylene and of propaldehyde in the presence of propylene are given. An examination of the influence of propylene and of nitric acid on the thermal decomposition of acetaldehyde forms Part IV of the series of experiments, which concludes with a comparison of a series of aldehydes.

Thermal Vibrations and X-Ray Scattering

MISS K. SARGINSON has continued her theoretical study of the effect of thermal vibrations on the scattering of X-rays (*Proc. Roy. Soc.*, A, 180, 305; 1942). The previous work on background scattering is developed in detail. Only the acoustical branches of the elastic spectrum can produce extra spots. The properties of an extra spot near a Laue spot can be derived from the elastic constants of the crystal, and explicit formulæ for the position and shape of the spots are given for cubic crystals with diagonal lattices. The applicability of the theory to Lonsdale and Smith's 'secondary spots' needs a special investigation.

Autelectronic Emission from Single Crystal Metal Points

FROM the research laboratories of the General Electric Co. a further instalment of the work on the distribution of autelectronic emission from single crystal metal points is presented by M. Benjamin and R. O. Jenkins (*Proc. Roy. Soc.*, A, 180, 225; 1942). The adsorption, migration and evaporation of thorium, barium and sodium deposited on tungsten and molybdenum are here dealt with. Migration occurs at relatively low temperatures, and for an optimum thermionic covering there is a unique distribution of the migrating atoms on the metal crystal. Certain crystal zones, are avoided by the migrating atoms. The atoms evaporate more readily from certain crystal zones, and the differences in temperature for complete migration and evaporation of the atoms lead to an explanation of the failure sometimes to observe migration with barium, from multicrystalline surfaces, where the difference between migration and evaporation energy is small. With thorium, where the differences are much greater, the migration is always observed. In the studies of thorium on tungsten and thoriated tungsten, it is found that the diffusion occurs through the crystal lattice along certain preferred directions. The final distribution of thorium is identical with that obtained by depositing thorium from an external source. The paper is illustrated by an extensive series of photographs with their interpretation superimposed on transparent paper. (Since the work was completed, Dr. Benjamin has been killed in a flying accident.)

THE DISCRIMINATION METHOD IN ANIMAL PSYCHOLOGY

By Dr. H. HONIGMANN

Department of Zoology, University of Glasgow

THE fact that an animal is able to discriminate between two stimuli is the foundation of a method used extensively in animal psychology. It is, however, open to various sources of error. While looking through a number of papers dealing with this method I found that some of these possible pitfalls are often not sufficiently realized.

(1) The danger of influencing the animal's choice by signs given unconsciously by the experimenter is well known. It is scarcely existent in lower vertebrates and probably absent in invertebrates. In the case of mammals and birds, however, it is still underrated. Often it is not the experimenter but the apparatus used that gives the secondary cue. Bingham[1] has told with admirable sincerity how his birds "outguessed" him in experiments on discrimination between two illuminated circles of different size, one of which had a constant diameter and the other a variable diameter. The position of both circles was constantly but irregularly changed to avoid training to position. The birds surprised the experimenter by their ability to discriminate between very slight differences in area. When they were able to discriminate between two circles of 59 and 60 mm. diameter respectively, Bingham became suspicious and made both circles equal. Even then the birds were able to discriminate between the variable and the standard circle, and it turned out that the cue was a scarcely visible streak of light caused by a minute crack of the box containing the electric bulb which illuminated the standard area.

While in many cases the experimenter becomes aware of the cue guiding the reactions of his animals, this source of error is often overlooked. The most striking results obtained in work with the so-called 'multiple-choice' method and quoted for years in all papers dealing with this problem are in all probability due to secondary cues, as I have pointed out elsewhere[2].

(2) Even in the absence of all crude secondary cues, and I have mentioned only one possibility out of very many, there is always the danger that the animals in question will discriminate between the two stimuli in a way differing completely from the experimenter's assumption. Very frequently errors are caused by the confusion of the objective stimulus with its subjective equivalent; for example, brightness, being a purely subjective concept, cannot be measured in objective physical units as intensity of radiation (=heat equivalent). Two colours, which have the same brightness for us under a certain condition of adaptation, etc., acquire a different brightness for ourselves when the objective intensity of both of them is reduced to a fraction of the previous values. This is a well-known fact, but it is often overlooked that the ratio of brightness might change in quite a different way for animals in exactly the same circumstances. Thus in many papers dealing with the 'discrimination of colours' the animals in question may have only distinguished between different intensities of light, instead of different wave-lengths.

(3) Apart from these possibilities, there is still another source of error in discrimination tests: an error in the interpretation of the motives responsible for the animals' choice. As this is a matter of primary importance, misjudgment in this respect appears especially dangerous. The simplest way to deal with this problem is to give a concrete example taken from Bierens de Haan's "Animal Psychology for Biologists"[3]. This very experienced and careful worker, by means of a typical discrimination method, trained a monkey to find food behind a door marked with a red circle. There was no food behind a second door showing a blue triangle. He gives the following description of his experiments (p. 41): "When the animal was well trained, I changed the blue triangle for a blue circle or a red triangle, leaving the red circle as it was. Had it been trained to go simply to the red circle, as I supposed it was, then there would have been no reason for the monkey to make errors now, as the red circle remained visible as before. Instead of this, the animal now made about 50 per cent errors—that is, it was quite confused. The only possible explanation of this sudden confusion, as all other circumstances remained the same, is that the animal was not trained simply to go to the red circle, but to go to the red circle in opposition to the blue triangle, so that, when this latter figure was changed, the red circle lost its meaning as a guide to the food. As soon as I showed the former combination of figures, the animal was again at home, and made no more errors."

E. S. Russell, in his "Behaviour of Animals"[4], has quoted the same passage as a typical example for a reaction "where the response was to complexes rather than to single features of the perceptual field".

I cannot agree with the interpretation that here the "complex effect" of the two stimuli is the "only possible explanation". It is quite possible that the animal had not learned to open the door with the red circle, but only to avoid the one marked with the blue triangle. The blue triangle, however, was not used again in Bierens de Haan's control tests. They were therefore incomplete, and should have been supplemented by offering the blue triangle (the negative sign) in conjunction with one of the signs not used for the training—the blue circle or the red triangle.

There is still another point. When only the blue triangle had obtained a "valence" (this valuable term has been introduced by E. S. Russell into animal psychology) for the monkey, in this case a negative valence, we should not expect the animal to be confused when this sign was absent, but just an unrestricted selection of the two doors according to chance as neither was significantly marked for the animal. If we now look back to the description of Bierens de Haan's experiments in his original paper[5] we find indeed no "confusion", which would manifest itself in hesitation or even refusal to make any choice, but just the contrary. Bierens de Haan says here (p. 730) that he found it most surprising that the monkey showed so little hesitation, when the positive sign was missing, and in most cases it made its choice at once when the screen covering the apparatus was lifted "as if nothing had been altered in the experimental conditions". This confirms my opinion that here only the negative sign had obtained a valence for the animal, and actually there was no confusion and no reason whatever for the monkey to hesitate when this sign was missing. As the two other stimuli had no valence—either positive or negative—they were selected without preference and thus the

50 per cent "errors" of the monkey are fully explained without the necessity of assuming a complex effect.

One could object to this explanation that it is improbable that a negative sign would obtain a decisive valence although there was no punishment, while there was a reward (food) in the case of the positive sign. This, however, is by no means uncommon. It is very instructive to compare these results with experiments carried out much earlier by Breed.[6] This author trained fowls to discriminate between colours, for example, black from blue. When selecting blue the birds were punished by an electric shock, while in the case of a correct choice (black) the only reward was that the birds could see or join their companions again. As the negative stimulus was here the "emphatic" one, Breed expected that the birds would react indifferently when the negative sign was replaced by a new one—and so it was, at least in the majority of the cases. Even the brightness of the colours did not matter at all as these birds reacted in the same way to white-blue as to black-blue—the response being one of "getting-away-from-the-blue-no-matter-what-the-other-colour." But this did not happen in all cases, for Breed found to his surprise in three out of eight birds that they responded "definitely and positively" to black, but not negatively to blue. These three birds were quite lost when white accompanied blue, although the training procedure had been exactly the same in both cases. "With these chicks black (+) seemed to be the guiding stimulus" (p. 69), that is, they acted only according to the positive sign although this was not the emphatic one.

Breed tried to summarize his results in a general statement. He was perhaps not quite fortunate in expressing it in the following words (p. 78): "Psychologically, it seems, negation is not affirmation". Apparently he wanted to say that if we train an animal to discriminate between two stimuli, the creation of a negative valence for one of them does not necessarily mean that the other one obtains automatically a positive valence for the subject in question—and vice versa. The importance of this fact for experimental work on discrimination is obvious.

To avoid any misunderstanding, I should mention that often a complex effect can indeed be primarily decisive in discrimination tests, for one need only recall the well-known experiments carried out by W. Köhler[7] on the "structural function" (the relative choice) present in the domestic fowl and chimpanzee. Here the response was definitely to a relation between two stimuli (for example, between two different shades of grey), but Köhler was much too careful to claim that this was the only possible way of learning. The learning effect fixed to absolute characters is in his opinion only of short duration, while the effect of the "structure of the pair" is better fixed. This difference in fixation, however, is by no means sufficiently examined and would no doubt provide material for interesting psychological work. For the time being we have therefore in every discrimination test to examine not only the effect of the pair, but also of each of its single components.

RECONSTRUCTION IN OXFORD AND LIVERPOOL

THE second part of the report of the Committee on Planning and Reconstruction of the Oxford Preservation Trust, which has recently been issued, makes a number of detailed recommendations. Turning first to the new civic centre, it is recommended that it should be located where the three roads from Headington, Iffley and Cowley converge, a sufficient area being also allocated for a proper shopping centre for the eastern half of Oxford, including a new covered market. The St. Ebbe's area should be replanned, the greater part of the site of the Oxford Prison, including the Castle Mound, being made into a public park. In the western section a new joint railway station should replace the present inconvenient and unsightly structures. In the central section the covered market should be removed, and possibly two new markets substituted, one in Castle Street and the other in East Oxford. Gloucester Green might become a square for shops and offices, while Holywell with Merton Street should preserve its present character.

In regard to surrounding towns and villages, Kidlington should become more self-contained, with better shops and social amenities. A number of villages in the vicinity of Oxford should be protected from industrialization and objectionable building, but there are in the district country towns which might welcome the advent of new light industries. The beginning of a protective girdle of open land around Oxford already exists, but early action is necessary to protect from building development a number of farms and playing-fields on the fringe of existing suburbs, together with several stretches of hill and woodland. This will involve some purchase of land in the public interest, but much will continue in use for agriculture, including market gardening.

To relieve the congestion in the centre of the city, it is essential to complete the northern and southern by-passes at the earliest date possible after the War. The northern section of an inner circular road which has also been under consideration by the City Council, with a new bridge over the Cherwell near the southern end of Mesopotamia Walk, would also be an advantage, but the difficult questions raised by the alignment of the southern section might be left for further consideration until the effect upon traffic of the various other measures contemplated becomes apparent. Other recommendations include a greater use of Cowley Station for passenger and goods traffic, doubling the single-track line to Princes Risborough, with an alternative fast railway service to London and elsewhere; provision of numerous public walks; improvements in the confused waterway system; proper control over the design of new or restored buildings, and the preservation of old houses remaining in the area of the medieval city; and adequate amenities, including a building for a proper health centre.

The post-war reconstruction of Liverpool was the subject of an address by Alderman A. E. Shennan, which has been published by the Liverpool Council of Social Service and the Merseyside Civic Society. The extensive damage which Liverpool has suffered from the numerous air raids has given it an opportunity of re-planning which it could not otherwise have hoped to see, and in commending Alderman Shennan's bold scheme, the Lord Mayor points out in a foreword that it provides a plan of central Liverpool which would make it a place worthy of the coming needs of post-war building on a grand scale. The broad street or avenue making a circuit from pier-head to pier-head, connecting the three railway stations and forming a ring from which traffic could easily move to the outskirts without crowding the centre as at present, would give an importance to the inner section of the City which it sadly lacks to-day. Moreover, the re-planning of the pier-head itself would give Liverpool at last a water-front of which it might be proud, and through which it would proudly welcome travellers from all parts of the globe.

The first proposal covers the dock area, whereby the Dock Road, north of its junction with King Edward Street, would virtually become a private service road on a combined dock and railway estate, extending the existing dock estate eastwards to Derby Road and Great Howard Street. These two roads would be converted into a wide artery capable of carrying all north- and south-bound through traffic along the line of the North Docks, and the Overhead Railway would be replaced by a more mobile system of passenger traffic.

A major item in the plan is an inner ring road which is regarded as the proposal which could confer the greatest benefit to the heart of Liverpool. It is a feature missing in the natural development of most towns. It would give added importance to Exchange Station, and the scope for architectural treatment which the expansion of the railway termini afford is greatly stressed by Alderman Shennan. There would be a direct connexion between Exchange Station and the Lord Street–Church Street shopping centre, while the proposals for the new civic centre, the heart of which is the tunnel entrance, provide for the reservation of the St. John's Lane frontage for civic buildings, to balance the Museum and Art Gallery, and to complete the growing of the stately beauty of St. George's Hall, while on the western side, buildings connected with the administration of the City would be sited.

The town hall, the two cathedrals and the pier-head are the subject of other planning proposals, and the scheme contemplates a general rectification of the existing street plan, control by zoning, provision of industrial sites, open spaces and linking the parks. The plan involves a long-term as well as a short-term policy.

There is no reason to doubt the ability of the people of Great Britain to seize the opportunities of re-planning which the War has given us, and these two examples of plans show a vision and vigour which are the best safeguard against the apathy and selfishness which led to London missing its opportunity of nearly three centuries ago.

ELECTRICAL PRODUCTION OF BULLET-PROOF STEEL

THE manufacture of bullet-proof steel is surveyed in an article by A. G. Arend in the *Electrician* of July 31. Formerly intended for helmets, bullet-proof steel was also made for breastplates in the closing stages of the War of 1914–18. When the latter were first proposed, a manganese-vanadium steel was employed containing some 0·90 per cent of manganese and 0·20 per cent of vanadium, and was prepared in Heroult three-phase electric furnacess Despite the purest possible metal being produced, results were not uniform, and a manganese steel was substituted containing 12 per cent of manganese, and 1 per cent of carbon.

Little has been done in the intervening years in the way of development, although vanadium steels have found extended use in automobile production. A maximum of 0·02 per cent is allowed for both sulphur and phosphorus; the small range of the other constituents precludes the use of anything but the absolute precision of control peculiar to the electric furnace. The vanadium constituent is important, and although ranging only from 0·15 to 0·25 per cent content, it allows of a light strong steel. The last approved bullet-proof steel, prepared in 6-ton Heroult furnaces, contained 2 per cent nickel, 1 per cent manganese, 0·20 per cent vanadium, 0·20 per cent silicon, 0·02 per cent phosphorus, 0·02 per cent sulphur and 0·42 per cent carbon. The admissible error was 0·05 per cent except with sulphur and phosphorus, which could not exceed the 0·02 per cent maximum.

The furnaces were not then equipped with automatic arc regulation, and gave trouble in the initial melting of scrap. Present-day furnaces are of smaller capacity and bottom connexions are omitted in the larger sizes to avoid the formation of cracks. Water cooling of bottom connexions, so far as the hearth is concerned, is now regarded as potentially dangerous.

There is a choice of design to-day between the direct arc and arc-resistance types of furnaces, the latter being preferred when a smaller charge suffices. Troubles with the smaller electrodes for 1-ton hearths resulted in the use of two-phase furnaces with bottom connexions, the current being supplied through Scott connected transformers. In comparison with the low operating voltages used for plain carbon steels, supply is usually switched on at 110 volts: with the cold scrap used in the charge, surging can momentarily raise the current as high as 10,000 amp. Since the refining period tends to vary, the energy consumption ranges from 750 to 825 kwh. per ton.

The carbon content following de-phosphorizing should be about 0·300 per cent, with the actual phosphorus below 0·02 per cent. Tapping temperature is important and after final additions have been made to the melt, it is only allowed to remain in the ladle long enough for the slag to rise properly, whereupon it is cast into ingots of about 8 in. by 14 in. cross-section, care being taken to avoid undue strains from shrinkage by chilling. Ingots are then rolled and shaped as required, undergoing any necessary heat treatment.

During 1914–18, two test methods were available for helmets and breastplates. The former, which were of 0·035 in. sheet, were subjected to the impact at 10 ft. of a bullet fired from a 0·44 Colt revolver with a muzzle velocity of 840 ft./sec. The breastplates, of 0·175 in. thickness, were expected to withstand the impact of a copper-sheathed rifle bullet fired at 50 yd. with a muzzle velocity of 2,140 ft./sec. In the former case the metal was considered to be satisfactory if the bullet did not make a dent of more than 0·5 in. in depth and 3·5 in. in diameter. Successful production of bullet-proof steel largely depends upon systematic furnace operation, and it is imperative that all electrical connexions function with precision to permit of continuous uniform working without temporary stoppages.

MANUFACTURE OF FERTILIZER FROM URBAN WASTES

By GEORGE BRANSBY WILLIAMS

THE importance of organic fertilizer in maintaining the humus content of soils, which is essential for growing crops in a healthy condition, is now widely recognized. Many definitions of the nature and functions of humus have been given, but the most practical is that given by Mr. G. V. Jacks in a paper read before the Royal Society of Arts on February 12, 1941; he said, "Humus does many things all of which can be summed up in the statement that it makes a mass of otherwise dead rock particles a suitable habitat for living plants. It is the substance which distinguishes soil from a mere geological deposit." The luxuriant growths produced by artificial fertilizers deplete humus of its essential elements unless an adequate supply of suitable organic manure is used to restore them.

It has for a long time been generally assumed that it is impossible to feed more than a fraction of the population of Great Britain on home-grown food, and the nation has resigned itself to seeing agriculture slowly decay until in many parts of the country landowners and farmers have been more concerned with the value of the land for building than with its fertility. Actually it seems that there would be no physical difficulty in growing the greater part of the food we require in our own country. The production of home produce has been in normal times an economic question, but in war-time it has become a vital matter on which the survival of the nation may depend.

If the quantity of food produced in Great Britain is vital, then so is the supply of an adequate supply of organic fertilizer. Both house refuse, and the sludge that settles out of domestic sewage, contain considerable quantities of organic matter that can be converted into humus by simple methods in a longer or shorter period. Sir Albert Howard has estimated that there is 10,000,000 tons of refuse in the controlled tips around the cities of Great Britain, and hundreds of thousands of tons of fresh house refuse are being removed from the urban areas each year. Much of this refuse is incinerated and its organic fertilizing ingredients destroyed, and the problem of finding waste land on which to tip the remainder is yearly becoming a more difficult one. The matter in the sewage amounts to nearly another million tons per year. A portion of this is discharged into the sea, and considerable expense is incurred annually in disposing of the rest by drying, pressing, trenching or digesting.

These materials, as first produced, are not in a suitable condition for application to the land, but they can be transformed into humus by composting. The system of composting urban wastes had its early development in India. Mr. R. D. Anstead related in a paper read in 1932 how, in the first instance, simple waste products, such as leaves, weeds, old straw and the like, were fermented. This method proved so successful that Dr. Fowler and others turned their attention to dealing with the refuse of Indian cities in the same way. The high temperature of initial fermentation kills all fly larvæ and all weed seeds.

Ordinary sedimentation tank sludge can be used. It has also been found that cover is not essential, for the process can be carried on very successfully in the open.

The large amount of cellulose in pulverized house refuse is just what is needed by the fungi and bacteria which synthesize microbial tissue in a manure heap.

A process for converting household refuse into fertilizer by inoculating it with a bacterial culture has been evolved by the Hyganic Company and is in operation on a large scale at the Kensington Borough Works in Wood Lane, London. Here it deals with about 100 tons of refuse per day from 180,000 persons. The process is rapid in action, but as exemplified at Wood Lane is expensive.

Simple composting or mixing in heaps on a concrete floor as carried out at Maidenhead is cheaper. The process of manufacture of the fertilizer is carried on at the sewage works. About 20 tons of refuse collected from a population of about 30,000 is delivered at the works daily. The house refuse, after picking, screening, magnetic separation and pulverizing, is stacked in heaps to a depth of about 4 ft. 6 in., the top surface of the heaps being left saucer-shaped; sludge with a moisture content of about 96 per cent is pumped daily on to the heaps. After four days, the heap is turned over on the concrete floor, then left for another three days. During this period active fermentation takes place, and the temperature rises to about 160° F. The compost is then removed to a maturing heap, here it remains for not less than four months. It is most important to mature the compost; if insufficiently matured compost is added to soil the material continues to immobilize nitrogen, and this action will compete with any plant life and lead to starvation of the crop. Sufficient maturing is only a matter of sufficient time; no additional turning is required. Neglect of this precaution in England has led to quite false ideas about the value of this compost. The price obtained for the fertilizer is from 7*s*. 6*d*. to 10*s*. a ton. The demand is greater than the supply.

The humus heap which has matured for three to four months is almost completely broken down into the condition suitable for addition to the soil. A noticeable feature is the absence of weeds, and particularly of the tomato plants which are common when sludge that has been dried on drying beds is used.

Very large sums of money are spent yearly in the urban areas of England in getting rid separately of two obnoxious waste products, namely, household refuse and sewage, without in most cases getting any return for the money. By mixing them together and passing them through a series of simple processes, not only is nuisance and expense avoided, but also a fertilizer is produced which is vitally needed by agriculture and for which a price can be obtained that should more than repay the cost of its production. The Maidenhead composting works give evidence that there is no serious difficulty in preparing the fertilizer, and it may be anticipated that in future many other towns will appreciate the simplicity and feasibility of the process. In particular it is reasonable to hope that those seaside towns which now turn crude sewage into the sea, fouling the foreshore and making bathing unpleasant and even dangerous to health, will introduce settlement, combined with composting of their refuse, and at the same time make use of the fertilizing value of seaweed. At the present time the need for such a fertilizer is urgent.

CAUSE OF THE NEW HAMPSHIRE EARTHQUAKES OF 1940

L. D. LEET has made an important contribution to this topic by his initiation of a hypothesis concerning the beginnings of the New Hampshire earthquakes of December 20 and 24, 1940, in the Ossipee Mountains district ("Mechanics of Earthquakes where there is no Surface Faulting", by L. Don Leet, *Bull. Seis. Soc. America*, 32, No. 2; April, 1942).

On the basis of the travel-time data on elastic waves from the Ossipee earthquakes, combined with the results of Griggs's experiments on rock deformation and fracture, Prof. Leet proposes the following hypothesis. A zone of radius roughly 20 km. initially unstrained and spherical, extending upward into the crustal layers to near the base of the granitic layer, was progressively distorted by a horizontal shear couple. When the strain reached a critical value for the material, fracture occurred near the original sphere's equator and was the source of the largest shear waves. Distortion by pure shear transformed the original sphere into an ellipsoid, which terminated short of the earth's surface, where fracture had to grade into folding and die out. At the upper terminus of the resultant ellipsoid's major axis, this process would produce a concentrated compressive force on the base of the granitic layer, which started the longitudinal waves. This implies simultaneous mass movement of translation of the upper half of the original sphere. The resultant compressive stresses developed in the granitic layer kicked back four days later and produced the second earthquake. The aftershocks died quickly, in part because of rapid healing of the fractures and in part because the region was brought practically to equilibrium by the second shock, since relief came in zones of flow which, unlike surface faults, have few, if any, irregularities to produce temporary frictional hang-ups as movement progresses. If this is true, the probability is that the Ossipee structure does not extend below the base of the granitic layer, for otherwise a mass movement of the plug, which is an important feature of the White Mountains structure, would have been expected to show up at the surface.

The evidence of recent years is definitely that regional forces are at work on new levels of activity in the north-eastern American province. No great stretch of imagination is required to detect an alignment of some of this activity, including the earthquakes of December 1940, along the trend of the major reservoir for the White Mountains magma series. On grounds of distribution alone, however, there does not seem to be a satisfactory basis for distinguishing between deep-seated magmatic forces in renewed activity and yield to glacial loading stresses along old planes of weakness.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEPUTY ENGINEER AND MANAGER of the Southport and District Water Board—The Clerk to the Southport and District Water Board, Town Hall, Southport (September 14).

FULLY QUALIFIED FOUNDRYMAN to act as SUPERINTENDENT in the College Instructional Foundry—The Registrar, Loughborough College, Loughborough.

FORTHCOMING EVENTS

Friday, September 11

PHYSICAL SOCIETY (COLOUR GROUP), at Imperial College, S.W.7, at 2.30 p.m. Mr. E. G. Savage: "The Teaching of Colour in Schools" (Lecture followed by informal discussion).

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Why Hitler? By H. Runham Brown. Pp. 20. (Enfield: War Resisters' International.) 3*d*. [68

Proceedings of the Royal Society of Edinburgh. Section A (Mathematical and Physical Sciences). Vol. 61, Part 3, No. 16: Simultaneous Linear Partial Differential Equations of the Second Order. By E. L. Ince. Pp. 195–209. (Edinburgh and London: Oliver and Boyd.) 1*s*. 3*d*. [78

Scientific Proceedings of the Royal Dublin Society. Vol. 23 (N.S.), No. 2: The Chemical Constituents of Lichens found in Ireland, *Cladonia impexa* Harm. By T. W. Breaden, Dr. J. Keane and Dr. T. J. Nolan. Pp. 5–10. (Dublin: Hodges, Figgis and Co., Ltd.; London: Williams and Norgate, Ltd.) 6*d*. [178

Geological Map of the British Islands, based on the Work of the Geological Survey. Third edition. Scale of 25 Statute Miles to 1 Inch. 36 in. × 26½ in. (Southampton: Ordnance Survey Office.) Uncoloured, 1*s*.; coloured, 2*s*.; mounted and folded in sections, 4*s*. net. [208

Other Countries

Proceedings of the United States National Museum. Vol. 92, No 3141: Scored Bone Artifacts of the Central Great Plains. By W. R. Wedel and A. T. Hill. Pp. 91–100+plates 7–13. Vol. 92, No. 3143: The Sardis (Georgia) Meteorite. By E. P. Henderson and C. Wythe Cooke. Pp. 141–150. Vol. 92, No. 3144: Rhopocrinus, a New Fossil Inadunate Crinoid Genus. By Edwin Kirk. ORGANIZATION OF SCIENCE FOR WAR

NONE of us likes this War, and men of science must especially hate it because they, perhaps more than most groups of professional men, realize how much their work, much of which was carried out with no thought of war, is now involved, and how much the fruits of their labours are often of necessity being prostituted to the immediate aim of destruction. Many of us supported the Herculean attempts which were made to prevent war; but those attempts proved futile, and now science is fighting this War. Nobel died a sad man because he realized how his discoveries were being utilized by mankind. It was, however, his good fortune, after failure in his own lifetime to inspire his fellow-men with the spirit of world citizenship, peace and goodwill, to be able to give to the whole world some means of fighting the persistent and diabolical application of his and other discoveries to warfare. Few men of science could do the same to-day, because science is a calling as well as a profession and not many fortunes are made out of it.

Looking back, however, men of science can justifiably claim that they have fought hard against the utilization of their discoveries for what amounts to the destruction of what science has materially helped to build up. Their greatest mistake was that they did not fight hard enough. They have spent too much time squabbling among themselves over such questions as to what extent science should be planned, if planned at all, and have not sought diligently enough to impress upon the public mind that they realize full well what the implications of their work might be and then act accordingly. Too often have the men of science of the past remained within the four walls of their laboratories, sometimes deliberately closing their eyes to the possible results of their work to humanity once such results have passed into the outer world.

Indeed, some men of science have gone farther than this. Being fully aware of the dangerous policy of letting anyone (probably not so public-spirited as themselves) 'cash in' on the results of their discoveries they have chosen to close their eyes to it in favour of what they claim to be the battle for the so-called freedom of science. Time and time again in these columns have we tried to impress upon men of science that they, above all others, must realize what the impact of their calling is upon society, and, even more important, that they must act accordingly. What has been the result ? Many have agreed with us that it is essential that men of science should be brought to realize much more than they do at present what are the social implications of their work. On the other hand, some have taken the opposite view and have gone so far as to issue warnings that if men of science persist in the so-called planning of their work then they will merely succeed in killing it.

The social, both national and international, relations of science, as indeed of all academic and other disciplines, must be the concern of all thinking men. This should not involve them in political party arguments as some seem to think, for science, if true to herself, cannot recognize party politics any more than she can acknowledge geographical boundaries to the great truths she discovers. The distinction between 'pure' and 'applied' science must go, and a good riddance, for it never was a logical distinction and has been the basis of much futile and wasteful argument. Those men of science who have expressed disapproval of scientific planning visualize, we think, planned science as meaning putting men of science in chains. This could never happen in the democracy for which we are fighting; but even if it did, then surely nothing but good could come of it provided such chains were guiding chains and not prison chains, and always provided that they were under the control of certain men of science themselves—trustworthy men who fully appreciated their duties to their fellow-men and who had the courage of their convictions.

Wars teach us much. This is the first totalitarian war we have experienced, though it took us some valuable time to realize it. By now, most of us have developed shrewd ideas of what we are, or ought to be, fighting for and the paths along which world reconstruction must travel once victory has been achieved. But though we know what we are fighting for and though many of us know what kind of world we wish to see established in the peace to follow, it is very essential to bear in mind one thing here and now; that is, we must win the War first, and we can do that only by fighting—fighting to achieve our immediate war aim, the destruction of Nazism and all for which it stands. One sometimes wonders if the many critics of policy adopted by Government and other authorities always take this into consideration.

With this immediate aim in view, science must be, and is being, planned, not only by men of science but also by those responsible for our war policy, war strategy (offensive and defensive), war production, and so on. It is certain that science is fighting this War the world over. In fact, it *is* a war of science whether we like it or not. We should only succeed in presenting platitudes if we attempted to give examples to illustrate this. Some idea of the views of our American colleagues, in this connexion, can be obtained from an article beginning on p. 310 of this issue.

In view of all this, sad though it may seem from the ethical and even moral points of view, it is actually a matter for congratulation that men of science have not only come forward and offered their services in the war effort, but have also pressed their claims in many quarters and even expressed indignation when their offers have sometimes not been eagerly accepted forthwith. There are, of course, men of science such as physicists, chemists, mathematicians, engineers, and so forth, whose qualifications have meant their immediate absorption into the nation's war effort. On the other hand, some branches of science have felt that they have been left out of it. It was originally the stated function of the Central Register, for example, at one time solely to find men for jobs: But that has now been changed, and if certain men of science have been able to prove their worth, jobs have been found for them. There are, however, even now, some scientific workers, especially among the biologists, whose positions might profitably be reviewed.

Furthermore, there is a tendency for individual, and groups of, men of science at times to urge the importance of this and that problem and press for an immediate inquiry, thus leaving the implication that those in authority are unaware of such problems and are therefore doing nothing about it. But this is not always the case. Though it is true that Government departments have at times betrayed a lack of awareness of what problems exist and what ought to be done, some men of science and even groups and associations have shown a lack of knowledge of what is already being done or, at any rate, a lack of sympathy with all the problems which might conceivably be involved. Of the many suggestions put out for the consideration of Government ministers and departments some show a definite lack of knowledge of what that minister or department is already doing. In this way, through not making certain of what has already been, or is being, done and not maintaining a sense of values, such men of science often defeat their own ends.

But in spite of all this, some men of science have been quite justified in claiming that their services are not being utilized as they should be, and many more have expressed concern over the failure of the Government to co-ordinate the scientific effort more efficiently. Of course, no Government can be expected to know all that science has to offer; hence a certain justification for the grouses and grumbles of some sections of the scientific community. On the other hand, men of science must not assume that just because the plans of the Government and its various ministries and departments are not going along the lines which they, individually or collectively, think are the right ones, the Government is therefore closing its eyes to the golden opportunities which science has to offer. A very keen sense of values is necessary, and above all co-ordination and organization within, and between, the scientific and other aspects of our war strategy are essential.

Yet the Government has never been above criticism where the utilization of science in the war effort is concerned, and some of its faults have proved to be serious ones. For this reason we welcome the announcement made on September 4 that

"In order to ensure that the fullest use is made of our scientific and technical resources in the field of production, the Minister of Production has appointed Mr. W. A. Stanier (Chief Mechanical Engineer to the London, Midland and Scottish Railway), Dr. T. R. Merton (Treasurer of the Royal Society), and Dr. I. M. Heilbron (Professor of Organic Chemistry, Imperial College of Science and Technology) to his staff in the capacity of full-time Scientific Advisers."

As a mechanical engineer, Mr. Stanier is well known. He was president of the Institution of Mechanical Engineers last year and is at present chairman of the Railway Executive Committee's Mechanical and Engineering Committee. Mr. Merton was formerly professor of spectroscopy in the University of Oxford, and his work carried out in the

University and in his private laboratory since has brought him an enviable reputation. Prof. Heilbron is professor of organic chemistry in the University of London (Imperial College of Science and Technology). His work has shown him to be interested in biological as well as chemical problems. Also, few chemists have had wider experience in connexion with the chemical industry than he. He has acted as scientific adviser in various capacities to the Ministry of Supply since the War began.

The official statement, in announcing these appointments, continues:

"The field of activity of these advisers will be co-extensive with the responsibility of the Minister of Production. They will keep in close touch with the scientific advisers of the Service and Supply Departments, and will be available to assist the departmental organizations of scientific research and technical development. They will not supersede the departmental organizations, which will, for instance, continue to be responsible for the examination of new inventions and technical suggestions in their own fields.

"They will be responsible to the Minister of Production, but will work under the immediate supervision of the Lord Privy Seal, acting on his behalf.

"These appointments have been made with a view to completing the existing organization for scientific research and development which has been carefully built up over a number of years and operated with outstanding efficiency.

"The Government have reviewed the whole position in the light of recent representations, and have decided that the creation of the post of Minister of Production affords the opportunity for this further measure of co-ordination which the Government believe will be to the national advantage."

To say the least of this announcement, it is an excellent example of democratic government, and those who have made representations to the Government recently can be assured that their efforts have not proved altogether sterile. Science has again raised its voice, and again that voice has been heard. The response of the Government will give considerable satisfaction. Our immediate aim is, of course, to criticize; but there is not a great deal to criticize. However, the statement that "These appointments have been made with a view to completing the existing organization for scientific research and development which has been carefully built up over a number of years and operated with outstanding efficiency" is, we think, a very bold one. Much scientific research has certainly been carried out along highly efficient lines, but it is doubtful if this can be said of all projects of research. Furthermore, even if all scientific research were carried out efficiently this does not necessarily spell satisfaction to the State, for it has to be organized and brought into line with the immediate needs of the country at war. Whether this has been done "over a number of years and operated with outstanding efficiency" and therefore, presumably, to the satisfaction of the majority, is questionable.

Furthermore, while it would be a pity to have any group of scientific advisers too large, this one possibly errs on the other side. We feel that at least five men of science should have been appointed, though we are doubtless safe in assuming that those who have been appointed will always know where to go for help and advice on any problem which might arise and which does not come within their own province. After all, in such a united country as this, so far as the war effort is concerned, the whole field of science is open to them. All three men are well known in the scientific world and therefore they themselves must know their scientific colleagues or their work.

It may be as well to note here that all three men are scientists. NATURE has never recognized any distinction between men of science and engineers; the latter are a class of the former. The tendency in some quarters to make an unnecessary distinction is confusing and sometimes leads to friction.

Some men of science, often eloquent in their criticisms and strong in their attacks, seem to fail to realize that scientific qualifications are not enough. Some scientific workers do not show the aptitude necessary for the type of work which Government departments might be demanding. Scientific achievement and aptitude must be considered hand-in-hand, and the newly appointed men will be the ones to do this, for they will know exactly where to go for the necessary information. Furthermore, we have little doubt that the men appointed will bring together a panel of advisers, individual or in groups (though not necessarily on paper), to whom they can turn for assistance whenever an occasion demands. Such a panel should remain a very plastic one, for no one, not even men of science themselves, can visualize exactly what problems will arise as the War proceeds.

That the newly appointed full-time scientific advisers will be under the supervision of the Lord Privy Seal, Sir Stafford Cripps, will also give considerable satisfaction, especially among men of science. As an officer of the State, Sir Stafford has already proved himself a public-spirited, keen, unselfish and efficient worker; but many will not know how fully he appreciates the value of science to society to-day, and above all to the war effort. Sir Stafford began his career as a scientific worker and carried out some useful research work under Ramsay several decades ago*. He has always since retained his interest in science.

Through Sir Stafford Cripps's keen appreciation of the work of men of science, and through his senior position in the Government, men of science should, via the new scientific advisers, be able to establish a more direct contact with the heads of the Fighting Services, the Air Ministry, War Office, Admiralty, Civil Defence authorities, and such Ministries as those of Fuel, Transport, Food and Supply, than has hitherto been possible. Thus men of science will not only be able the sooner to grapple with problems posed to them, but, just as important, their own suggestions and ideas might well receive a more sympathetic hearing. Through Sir Stafford and his advisers science will be able to place its help and advice in the quarters where it is urgently needed without having to waste valuable time explaining its implications and importance.

---

* "The Critical Constants and Orthobaric Densities of Xenon", H. S. Patterson, R. Stafford Cripps and R. Whytlaw-Gray (*Proc. Roy. Soc.*, A, 86, 579; 1912).

The scientific point of view is an important one in modern war policy and strategy, but not all non-scientific men have it. In fact, some of them, including certain ones in authority, have demonstrated impatience with, or ignorance of, science; but this cannot be said of Sir Stafford Cripps. It is known by many that he is very keen that science should take its rightful place in the forefront of the war effort.

This Government announcement is, therefore, one of the most encouraging that have been made during the War. It should now be less difficult to ensure that scientific and technical advice of the highest calibre be forthcoming when and where it is most urgently required. Men of science never willed or wished for this War any more than the rest; but, since it is inevitable, then men of science wish to play their part to the fullest of their capacity in helping to win it. Above all, they naturally want to be sure that their efforts are being appreciated and utilized to the utmost. Doubts concerning this have frequently been justified, for Government circles are not the only ones who should be aware of the importance and potentialities of science. The lay public should be more familiar with the scientific war effort. As it is, the layman seldom learns anything unless it is sensational or until something goes wrong. Even this announcement, important though it is, received only a bare mention on the radio and was not noted at all, or only casually mentioned in such a way as to tell the reader practically nothing, in the more popular newspapers.

Even at this stage, therefore, and taking a very long-distance and comprehensive view, it seems that the tail is wagging the dog. But the need is urgent, and at any rate something has been set in motion. If science were taught in our schools as a social study rather than as it is—a vocational exercise of little use to the majority of students—then the public as well as authoritative appreciation of the value of science to man during peace as well as war would become axiomatic and men of science would not have to put up the strong fights which are at times necessary, as things are.

Absorption of these three outstanding men of science into the higher grades of the war directorate has shown that those in authority have once more recognized the indebtedness of the country to science as a means of fighting and winning the War. Especially is this so in that science will be more able now to help to further the interrelationship of production with strategy. It is a good beginning in the right direction; but it is only a beginning. These men of science will have as their main task the co-ordination of all scientific work, and no doubt they will see that any scientific workers who might prove useful but have hitherto been overlooked will henceforth be used in the common effort. It is scarcely likely, however, at this stage of the War, that many men whose qualifications are of the first class and of direct value to the country at war are still not in harness. We have repeatedly claimed, however, that the men of science in the various Service Departments and the many other Ministries and Departments which need the aid of science should have easier access to their scientific counterparts outside, and vice versa. Though the new advisers will not wish to be inundated and hampered at the outset with unsolicited suggestions, they will now have a splendid opportunity for bridging this gap which has been all too prominent in the past. They will now be able to see to it that no loophole is overlooked, no claim ignored or discarded before having been thoroughly examined by those qualified to judge, and, by co-ordinating and periodically reviewing the scientific work of the country, that no wasteful overlapping of effort goes on unquestioned.

Some of us would have preferred that the scientific advisers now appointed, especially since their new duties will occupy their full time, were entirely free from any departmental organization such as the Ministry of Production. Further criticism in this connexion has been made by the Parliamentary and Scientific Committee (see p. 316). But this is happily offset by the statement that they "will keep in close touch with the scientific advisers of the Services and Supply Departments and will be available to assist the departmental organization of scientific research and technical development". Furthermore, the supervision of the Lord Privy Seal should do much to prevent their work being canalized too much. The work of these men will be prodigious, but of the utmost importance. The men themselves are doubtless equal to the job, but the extent of their success will depend in no mean degree upon the way in which the non-scientific authorities react to, and collaborate with, them. The same scientific spirit must permeate the whole organization of production and strategy.

At present, we are fighting as one of the United Nations to destroy the hideous forces at work in many parts of the world seeking to impose their will on all peoples. This is, and must remain, our immediate aim until such evil forces are eliminated and certain victory is achieved. To do all this in the minimum of time and with the maximum of effort, much of our peace-time science has to be shelved, and the rest organized and planned. Surely then an analogous form of planning will be necessary in the great fight which will follow the armistice—the fight to establish a world based on the democratic principles expressed in the Atlantic Charter and reiterated often enough since its announcement a year ago. As emphasized by President Roosevelt recently (see p. 316 of this issue), victory is essential but not enough; we must ensure the 'four freedoms' for generations to come, and it will require bold vision, intelligent planning and hard work.

In all the announcements made since that time, perhaps freedom of conscience looms up as the most important, for, as Thomas Mann recently said, a general work of spiritual restoration will have one of the first calls after the War; but next to this is surely freedom from want, for it will be useless to preach this or that principle, or to tell of the necessity for collaboration by subjugating selfish ends, to a people who is starving and shivering and in constant dread of extermination through lack of the simple necessities of life. Freedom from want is therefore the most comprehensive of all the freedoms, and as Sir John Orr has so aptly pointed out, this freedom must be among those first things which will have to come first.

In this fight for establishing freedom from want, science will have to play a very important part. In fact, its aid is now being invoked in the preparations already being made for dealing with the acute problems for which we shall have to be ready immediately hostilities have ended. To do all this efficiently and quickly, science must be properly planned and organized so that it can play its part efficiently and not along those haphazard lines which have so frequently been characteristic of it in the past. This is one of the conceptions which the War has forced upon us. While we must never condemn any piece of scientific work because we cannot attach any immediate utilitarian value to it, at the same time men of science must recognize their duties to society and thus be willing to be properly organized so that they give the maximum of service to the community, to the State and to the world. Sir Stafford Cripps and his newly appointed scientific advisers form an excellent example of what can be done in war-time. Let us hope that the lesson will not be forgotten in the peace to follow. Here we have science organizing itself with the help, but not the coercion, of the State.

ORGANIZATION OF POST-WAR RELIEF IN EUROPE

AN admirable report of a Study Group of the Royal Institute of International Affairs entitled "Relief and Reconstruction in Europe: the First Steps", outlining and relating to one another some of the immediate practical problems which will confront Europe when the War ends, makes its appearance when leading American statesmen have indicated their firm support of the broad policy laid down by Mr. Winston Churchill in his declaration of August 20, 1940, in connexion with the sending of relief to Europe. The report is a preliminary survey of the specific problems, of a general as well as a technical nature, which are involved in that policy. The studies on which the report is based are limited to Britain's policy towards Europe.

Mr. Churchill's declaration was followed by the declarations of the Allied Governments at a meeting at St. James's Palace on September 24, 1941: that it was their common aim to secure that supplies of food, raw materials and articles of prime necessity should be made available for the post-war needs of the countries liberated from Nazi oppression, and that while each of the Allied Governments and authorities would be primarily responsible for making provision for the economic needs of its own peoples, their respective plans should be co-ordinated for the successful achievement of the common aim. This aim of social security abroad no less than at home has been affirmed repeatedly by Mr. Eden as an objective of British foreign policy, and in his speech at Nottingham on July 23 he pointed out that the first task would be to feed the starving populations. There was also, he said, the problem of enabling devastated, impoverished and economically undeveloped countries to restart their agriculture and industry. Here two principles should govern the relations between such countries and those more highly developed: receipt of financial and economic aid must not result in any loss of independence for any country; and any form of assistance or guidance given to a country unpractised in the art of self-government must be such as to help it to achieve its own development.

The recent Washington Conference led to a scheme for ensuring that large supplies of food will be available for distribution when the time comes, and since the establishment of the bureau for collaborating in framing estimates of requirements of foodstuffs, raw materials and articles of prime necessity agreed upon at the Inter-Allied meeting on September 24, 1941, Russia has entered the Allied Councils. Obviously, her representatives will be specially fitted to give guidance on relief problems in eastern Europe. Moreover, the United Nations will also be able to call on the help of such surviving machinery of the League of Nations as the Economic and Financial Sections and of the International Labour Organisation.

Neither relief nor reconstruction, the report points out, can be carried out in a state of anarchy. The most urgent task of all, the transportation and distribution of food, depends on the existence of a minimum of order, and while in some countries the objects of the Allies will be achieved in association with a Government which enjoys their confidence and co-operation, in others their association with what purports to be the governing authority will require careful thought. Moreover, publicity as well as policy will be important and should be the subject of Allied consultations. The execution of measures of relief will require the constant use of publicity to give information and instruction to the people concerned. Allied control of broadcasting and news services and propaganda organs will be necessary in countries under military occupation, or through which Allied lines of communication pass, first as a direct military measure, secondly to prevent propaganda likely to frustrate the execution of Allied policy; and thirdly, to foster in ex-enemy countries such constructive and co-operative tendencies as exist.

This problem of authority and order is discussed in considerable detail with reference to Germany, where the difficulties are likely to be greatest. The analysis is on lines similar to that of a Planning (PEP) broadsheet issued last year, but stress is laid on the necessity that nothing should be done or permitted which conflicts with the cardinal aim of effectively dissolving German armed power. While the situation in Germany at the end of the War may well be one of chaos, tempered more or less by force of bureaucratic habit, the actual task of control may not be so difficult as it seems. A far-reaching military occupation will undoubtedly be necessary, and apart from disarmament, which must begin at once, the Allies must be prepared to accept heavy administrative, military and economic burdens if the opportunity of making Europe secure is not again to be thrown away.

If effective immediate help is to be given, plans for action in the economic, social and technical fields must be drawn up in advance, so that they may be put into operation simultaneously with measures for restoring order and authority. Last-minute improvisation, though in some respects unavoidable, may lead to confusion. Similarly, it is true that, in view of the uncertainty of the future, the plans drawn up must be flexible and will require revision from time to time.

The main task will be to organize food relief and health measures, and the report urges that the only hope of achieving rough justice in the allotment of priorities would be to regard Europe, or those parts of Europe to which we have access, so far as possible as a whole from the beginning. This will demand an important moral and intellectual effort of the more favoured peoples, and particularly cognition by the politically effective groups that a community of interests between the European peoples exists and demands this first instalment of practice. In point of urgency of need, no real distinction will be possible between the supplies required to meet immediate human wants, such as food, clothing and medicaments, and supplies of seeds, fertilizers and certain kinds of raw materials. An adequate relief policy must provide both; but whatever can be done beforehand to settle the major aims of policy will increase the chance of effective immediate action.

The report recalls, in sufficient detail to enforce this point of the necessity of planning relief in advance, the handling by the Allies of the re-victualling of Germany after the War of 1914–18. While the financial and political conditions on which Germany should receive relief in accordance with the estimate of her needs should be determined beforehand so far as possible, the character of the immediate measures will be determined also by the views which may be formed on the economic future of Europe, and on the institutional framework which it is desirable to establish. It is already widely recognized that both national and international organizations will be required, and the report elaborates the steps by which there might be developed a Reconstruction and Supply Authority, with wide powers and a flexible organization, from the Inter-Allied Bureau and Committee to which reference was made at the Inter-Allied meeting on September 24, 1941. This Authority, working with and through the local authorities, whether national governments or other serviceable elements, should be capable of mobilizing the resources of technical knowledge, co-operative will and administrative capacity wherever they are found. Its activities will of course require co-ordination with those of the Armistice Commission or other inter-Allied authority responsible for the re-establishment of order and the disarmament of enemy States.

The experience of 1918 emphasizes the importance of a clear understanding on the vital matter of organization well in advance, and whatever use may be made of existing machinery, its efficacy in action will largely depend on careful planning, the first general object of which is to form, and constantly revise, an estimate of the actual changing situation in Europe and what is needed to meet it; the condition and probable needs of agriculture; the state of transport, both ocean-going and internal; the state of health, particularly with respect to deficiency diseases and the risk of epidemics; refugees, transferred labour and other movements of population; financial position; raw materials and plant necessary to restore peace-time production; administrative personnel likely to be available—all these will require estimates. Much guesswork will obviously be inevitable, but it should be reduced to a minimum.

It is probable that fairly accurate provisional requirement programmes could be prepared for most countries by the Bureau, and estimates made of the supplies likely to be available to meet them. Such programmes should be prepared, where practicable, on the basis of regions dependent on particular ports, so that all shipments to the same region may be bulked, thus enabling account to be taken of local supplies and allowing the use of local surpluses for distribution in that region. In estimating requirements, use should be made of recent scientific work on standard diets, and to meet the urgent demand for supplies, large stocks must when possible be held in readiness. A beginning has already been made with the establishment of a Ministerial Committee on Export Surpluses. Flexibility will be essential if the best use is to be made of the available supplies and shipping.

From food and supplies the report turns to the question of health, and against the gloomy picture of widespread epidemics and an increase of disease generally, especially those directly or indirectly connected with malnutrition, it sets the various organizations which will be available to aid the national health services. On this point of organization it is emphasized that, while relief work under the direct control and supervision of the body providing relief is the easier and may be necessary in the initial stages, it is essential to operate as soon as possible only through the Government concerned and by utilizing that Government's machinery. Secondly, the control of starvation and such diseases as may be expected after the War depends primarily on transport, economic reconstruction and agricultural recovery, and only secondarily on medical personnel and drugs. Any medical relief organization should be closely linked from its inception with these three branches of relief work.

The report makes the third point that medical relief work must be regarded as part of the work of a future international body and should become part of this organization as soon as it is created. It is suggested that on the conclusion of hostilities, use should be made of the Health Organisation of the League of Nations which, with greatly reduced personnel, still operates in Geneva. From some points of view this would be a rapid and efficient solution of many of the urgent medical problems that will at once arise. Apart from this question of deciding what type of central co-ordinating organization is to be used for urgent medical relief work, the immediate tasks are to encourage among the voluntary organizations action designed to co-ordinate post-war relief measures and to examine the possibility of building up supplies of medical relief stores.

In regard to transport, the importance of relief convoys and personnel being able to move freely across frontiers without being held up unnecessarily by Customs and other formalities is urged. Such measures as a waiving of national road transport licensing systems and the removal of other obstacles to through transport of all kinds are desirable. Much greater co-ordination will be required among air communications, which should gradually pass into civilian hands as soon as possible. In regard to movements of population, disorderly dispersal, whether in camps or in large industrial undertakings, should be prevented by military or other Allied officials on the spot with power to provide for immediate needs and instructions for the workers to remain where they are until proper arrangements for their transfer can be made. Alternatively, instructions should be given in advance, if possible, to trade union or other leaders through their national Governments or their trade union organizations.

The relief and reconstruction problem is a supply problem, and financial considerations in the narrower sense will play only a secondary part. Broadly speaking, those providing the supplies will in the first instance have to take the responsibility. A positive supply policy based on priorities in relation to needs will be required ; even major financial questions should not be allowed to cause delay. The report indicates briefly a number of the measures which will be required, such as limitations on personal expenditure by rationing, canalization of investment and control of the capital market. There will be no orderly procedure by which Europe, having subsisted on outside relief for a brief period of convalescence, will then set itself to reconstruct its peace-time economy. The two processes will be simultaneous and inextricable, though later, one will absorb the other. In regard to agriculture, the Reconstruction and Supply Authority could probably perform a valuable service by providing technical advice, but to form an adequate estimate of the requirements of industry even for the immediate post-war period will demand a clear view of long-term economic policy. What is important is that the study of these questions should be undertaken at the earliest possible moment. Meanwhile, the evolution of the actual situation in Europe should be closely followed, and as long-term policy becomes more clearly defined, at least provisional opinions should be formed as to which tendencies should be reversed and which maintained, so far as the decision rests in Allied hands.

The urgency of planning for post-war reconstruction is demonstrated quite as conclusively in a further monograph, also issued by the Royal Institute of International Affairs, under the title "Medical Relief in Europe : Questions for Immediate Study", in which Dr. Melville D. Mackenzie gives an excellent though brief outline of some of the medical consequences of war and of the measures which a medical relief organization must be equipped to apply. Starting with a review of the factors, such as movements of populations, agricultural breakdown, transport difficulties and general economic strain on the population, impairment of public health and hospital services, which contribute to post-war medical problems, Dr. Mackenzie draws effectively on the experiences of relief work in 1919 and the following years to emphasize the need for a central medical authority covering the whole of Europe and prepared to go into action as soon as hostilities cease. On this question of organization he reiterates the arguments advanced in the report already quoted, but goes into further detail as to the problems which could be dealt with by a Medical Committee before the end of hostilities. This will include the collection and pooling of reports on medico-social conditions in Europe, the reconstruction of medical services, equipment and stores, the determination of standard rations, and the study of the medical needs of special groups.

Dr. Mackenzie then proceeds to discuss in some detail the special problems which may be expected to arise from malnutrition, typhus fever and malaria, and the preparation which might be made to deal with the situation. There follow admirably argued concise chapters on the necessity for the resumption of international health work in the light of the results achieved during the last twenty years, and on considerations relating to the re-establishment of a permanent international medical organization. These alone are of interest to every scientific worker, and they fully substantiate the conclusion that the urgent medical problems which will require solution the moment hostilities cease can already be discerned so clearly as to make immediate action both possible and essential.

It is true that the form of permanent constructive work in the sphere of international medicine depends so much on political, economic and social developments in the post-war period that any attempt to envisage it on more than the broadest lines is premature. Much, however, can clearly be learned from difficulties encountered, successfully or unsuccessfully, in the past ; and it is equally clear that only through international collaboration can the fullest use be made of our neighbours' and our own knowledge in the control of ill-health throughout the world. Solely by such co-operation can research be co-ordinated to avoid waste of effort, the spread of epidemics checked, and clinical and administrative knowledge pooled for the benefit of all. The nature of the most effective permanent machinery, how and when it can be created, and the exact tasks it should undertake, are questions linked with the future welfare of every community. Even in the present crises, they cannot fail to engage the deep thought of men of vision in every community.

These two publications of the Royal Institute of International Affairs are a sufficient answer to those who would defer consideration of planning for post-war reconstruction, either on the ground that attention must not be diverted from more urgent tasks or that the situation which such plans must meet is still unpredictable.

DEDUCTIVE COSMOLOGY

Time and the Universere

A New Basis for Cosmology. By Dr. F. L. Arnot. Pp. 76. (Sydney: Australasian Medical Publishing Co., Ltd., 1941.) n.p.

IN recent years it has been suggested that the laws of Nature can be reached by deductive methods instead of by inductions from observation. We may, with Eddington, assert that the chain of deduction starts from epistemological premises or, with E. A. Milne, that it begins with axiomatic statements defining the character of the system to be studied. Opinions differ widely regarding the value of the deductive method. If it is to be adopted, however, we may well ask that the author of a deductive theory should fulfil the following requirements. First, he must himself be aware of all the axioms or premises which he employs. If he is not, there can be no guarantee that inductive premises have not unwittingly been incorporated into the theory. Secondly, the axioms should be clearly recognized for what they are. They should not be introduced piecemeal in the course of the argument under the guise of deductions from the theory previously developed. In this respect, the model is Euclidean geometry, which begins with a statement of all the definitions and axioms that are afterwards used. Thirdly, the theory must be self-consistent and, naturally, free from mathematical mistakes. Under this heading we may also ask that consequences deduced from the theory should either be capable of check by observation or, if this is impossible, that they should at least be plausible.

We may attempt an analysis of Dr. Arnot's cosmological theory in the light of these principles, since it is of the deductive type. The author claims that his theory is based on two axioms only. First comes the axiom stating that there are two scales of time, a t-scale and a τ-scale, related by Milne's formula

$$\tau = t_0 \log(t/t_0) + t_0, \quad . \quad . \quad . \quad . \quad (1)$$

where t_0 is the present moment on the t-scale. The τ-scale is, by hypothesis, used in mechanics and physics generally. The t-scale is a scale which gives a finite age for the universe. The second axiom is the principle of the conservation of the energy of the universe as a whole.

It is impossible in a short review to deal with all the points raised by Dr. Arnot's theory. It will be sufficient to consider his three fundamental results in turn. His first result is that the velocity of light is constant on the τ-scale (c_0) and on the t-scale is c, where

$$c = c_0\, t_0/t, \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and is therefore variable. The two axioms stated above do not however give the result: a third is introduced, apparently unwittingly, namely, that the measurement of distance is independent of the time-scale. This is contrary to the principle of special relativity, where transformations from one time-variable to another are not independent of spatial transformations. Yet at a later stage in the theory Dr. Arnot sees no inconsistency in using results deduced from the Lorentz transformation in his theory. However, it might be possible to prove that the transformation (1) does not imply spatial transformation. The red-shift of the spectral lines of nebulæ at *fixed* distances apart is deduced from (2). But not without the introduction of another axiom (on p. 34), this time presented as if it were a deduction from the foregoing part of the theory. This axiom states that the emission frequency of a photon is independent of the time of emission t. The reader cannot but feel that *ad hoc* assumptions are being made in order to account for the red-shift without appealing to the idea of velocity.

Dr. Arnot's next result is that the number of particles in the universe varies as t^2 if the t-scale is used and is constant if the τ-scale is used. This follows from the principle of the conservation of energy for the universe as a whole, from the result (2) and from another additional axiom, namely, that the mass of the electron is the same on the t-scale and the τ-scale. No satisfactory explanation is given of why a change of *time-scale*, which is equivalent to directing one's attention from one clock to another working at a different rate, should alter this *number*. Moreover, it is necessary to suppose that, when the t-scale is used, particles are being created as t increases, but that this creation ceases as soon as an observer chooses to use the τ-scale. The correct conclusions at this stage would seem to be that the axioms so far used lead to a result which is not only incapable of observational check but is also in itself incredible, and that another set of axioms should be tried.

The last result which lies at the basis of the theory is a value (ct) for the radius of the Einstein universe. This is obtained by a mathematical fallacy which consists in confusing the "radius" of 3-dimensional spherical space with the radius of a spherical volume in Euclidean 3-dimensional space.

In justice to Dr. Arnot, it must be said that his book is a posthumous work. Had he lived, he would no doubt have noticed the inconsistencies and gaps in the argument which exist in the work as it stands, and he would have corrected them. As it is, his book serves to point the moral that the way of a constructor of deductive cosmologies is very hard, and is beset by pitfalls into which he may plunge without being aware of doing so.

G. C. McVittie.

INTRODUCTION TO ATOMIC PHYSICS

Introduction to Atomic Physics

By Dr. S. Tolansky. Pp. xii+343+5 plates. (London, New York and Toronto: Longmans, Green and Co. Ltd., 1942.) 15*s*. net.

THE purpose of this text-book is clearly defined in the foreword by Sir Lawrence Bragg. It follows from the belief that a student should be introduced to the great basic advances in experimental and theoretical physics in recent years in his second rather than his final year of undergraduate study. The contents of the book are then intended to form a background to the next year of more intensive treatment.

Many teachers will sympathize with this view, but will also appreciate the difficulties which confront an author when he sets about his task. There are difficulties of choice in such an enormous field of material, of decision as to the depth of treatment, and whether, if superficial or highly condensed, it can be of material benefit to a student at this stage. How far he has succeeded in arriving at a satisfactory solution of these problems may be a matter of opinion. At least it has appeared in print during a quiescent period of publication of new results in this field, when there is little danger of data becoming out of date while the book is in press.

Much of the contents will be of value to the student at this stage. The book has nineteen chapters, and, in addition to stock material which every such text-book must include, there are chapters on the quantum theory, the structure of crystals, the wave mechanics, cosmic radiation and the positron and meson, and relativity.

The two chapters on gaseous conduction and discharge, compared with other text-books, are considerably abbreviated. This is reasonable provided that the student is not led to think that a given subject is quite cleaned up when in fact it is still in a confused state. The paragraphs on recombination are somewhat misleading in this respect. Also the original method of deriving an equation for sparking potential due to Townsend is given. But it is now generally held that ionization by positive ions in weak fields is very improbable and that secondary emission from the cathode must be invoked instead to explain the maintenance of discharge. An equation agreeing equally well with experiment can be derived on these lines.

In Chapter 3 the introduction of a recent precision method of determining e/m is welcome, as well as the summary of measurements of Avagadro's constant. Similarly, the chapter on positive rays is good, though Fig. vii referred to in the text is not included in the plate.

In a short chapter on the quantum theory, proofs are given of Planck's equation, Debye's expression for specific heats, as well as the Bohr hydrogen atom. Since the book is based on experience of lectures on these lines in Manchester, one must conclude that this abbreviated treatment of black-body radiation and specific heats has been found to be successful. I myself would have been content with a more descriptive summary at this stage with emphasis on experimental results, leaving the full theoretical treatment for one bite in the following year. But this is merely an individual view, and the volume loses no interest through provoking this type of comment.

In Chapter 6, on the thermionic effect, one welcomes a descriptive reference to the modern theory of electronic states in solids. It is right and proper that students should realize that these concepts can be applied to metals and insulators, with which they are so familiar in the laboratory, as well as to atoms. But students may be puzzled by the integral on p. 110 as the text is worded. It is also questionable whether the 'shot' effect could ever give a precision value of electronic charge. The experimental values so far obtained show wide divergences. In the chapter on atomic spectra the author can speak with special authority. The student will find it tough going and is called upon to accept a number of statements without proof. But with the exception of the Zeeman effect, to which surprisingly scant reference is made, the meat is all there for the good student prepared to dig into it.

The chapters on X-rays and the structure of crystals contains much useful information, and in the next chapter student readers are introduced to the difficult subject of wave mechanics. It is to be hoped that they will complete the chapter still imbued with humility, and not be tempted to talk glibly about it. But the statement of the conditions under which Schrödinger's equation can be solved (p. 199) requires correction.

The greater part of the remainder of the book is taken up with radioactivity and the nucleus. The material is up to date and well selected, and students will read it with interest, not only because so much of it is experimental in background and therefore not difficult to grasp at this stage in their mathematical training, but also exciting. Having got them into this atmosphere, the author pulls them up sharply by a concluding chapter on relativity.

In brief, the selection of material is interesting and in many respects novel. But the book shows signs of hurried writing. There are a number of errata which have not caught the eye of the proof readers, and should have been added to the list on p. 1. Here and there the text is also rather loose. But the task of writing it under the pressure of present conditions calls for some allowance in such matters, and one may anticipate a new edition at an early date with emendations. A. M. TYNDALL.

ADVANCES IN MEDICINE

The March of Medicine

(New York Academy of Medicine: Lectures to the Laity, No. 6, 1941.) Pp. xiv+154. (New York: Columbia University Press; London: Oxford University Press, 1941.) 13*s*. 6*d*. net.

THIS volume contains six lectures devoted respectively to: humanism and science, by Dr. Alan Gregg, director for the medical sciences, Rockefeller Foundation; Paracelsus in the light of four hundred years, by Dr. Henry E. Sigerist, director of the Institute of History of Medicine, Johns Hopkins University; psychiatry and the normal life, by Dr. William Healy, director of the Judge Baker Guidance Centre, Boston; philosophy as therapy, by Dr. Irwin Edman, professor of philosophy, Columbia University; the promise of endocrinology, by Dr. Oscar Riddle, Department of Genetics, Carnegie Institution of Washington; and "What we know about Cancer", by Dr. Francis Carter Wood, director of the Laboratories, St. Luke's Hospital, New York City.

Dr. Gregg maintains that humanism offers much to science and especially medical science on the occasions when the physician finds science inadequate for the patient's needs and should call in the help of literature and the arts. Dr. Sigerist declares that while Paracelsus's contributions to medicine were of a totally different kind from those of the other great physicians and surgeons of the Renaissance, he made a number of valuable contributions to medicine, particularly as regards treatment, into which he introduced many chemical remedies. According to Dr. Healy, the time is ripe for psychiatry to take a lead in educating the normal man to know more about himself "for the sake of his own self-direction in social interrelationships". Dr. Edman, while not asserting that philosophy is a substitute for medicine, logic for surgery, or ethics for antiseptics, declares that philosophy is therapeutic in the sense that it is both sedative and stimulant, while the good physician is a kind of family and social philosopher. Dr. Riddle foretells that in the future endocrinology will add to human efficiency, normality, understanding and health. In conclusion, Dr. Wood shows that an enormous advance has been made in the treatment of cancer, especially in early cases, owing to the technical developments of surgery and the discovery of the destructive effects of radium and X-rays upon malignant tissue.

SCIENCE IN PEACE AND WAR*

By WATSON DAVIS,
Director of Science Service, Washington, D.C.

IN every sense this is a scientific war. On the fighting fronts, precisely built machines of defence destruction are manned by men expertly trained and laboriously supplied. On the home fronts production, transport and world economic strategy are the prime concern. Backing up this gigantic war effort are knowledge, thought, planning and research. Of particular importance is the scientific research, not just of to-day but of past years.

Unfortunately, the layman is usually oblivious to the scientific basis of our civilization until something goes wrong. To people without the vision and power that experiment and interpretation of experiment bring, the universe is a static, unchanging, finished creation which, nevertheless, rushes on and leaves them hopelessly behind. That is what has happened and will happen to individuals or nations without the precious ferment of scientific research. All tradition, lore, or musty mores are hopeless before the onslaught of new ideas, whether those ideas project a panzer attack or give a new mode of peaceful living to the world.

The scientific method in one sense is completely divorced from social consequences. Men of bad will can, with unenviable cunning, use the priceless, time-tested, experimental method to fashion offensive weapons which can be used to annihilate the environment and the people from whom true science must bring the continuing progress of the world. The metallurgist who makes possible a fine, keen butcher knife of stainless steel, a useful product of his technology, can of himself do little to prevent the use of that knife for murder by a mad butcher.

In another sense, the utilization of the resources of the world, including the knowledge and methods and mechanisms produced by science, is a real concern to those who are scientifically creative. It would be logical and not too much to expect that men of science take more than a democratically average interest in preventing destruction and aggression, misappropriation of our material resources, the distribution of good things of this earth among all the peoples, and the assurance of that essential minimum of food, clothing, shelter, education and freedom to all. This means that men of science and engineers must be more than creative specialists; they must be leaders in living and social organization, within the limits of their abilities.

Science can greet with equanimity the unreasoned criticisms that sometimes come to it, stating that science has created new and more deadly weapons. Of course it has. It has created mechanisms and devices for offence, as well as defence, just as it has brought into being many new homely, peaceful things of life. From the earliest days of war, even before lance, sword, and bow-and-arrow gave way to the chemistry of gunpowder, the major developments of war were the creation of science. Smokeless powder, the rifle, artillery, the submarine, high explosives, the aeroplane, armour, poison gas: all of these are from science's armoury.

There should be no undue surprise if and when novel and unconventional weapons come to light in this War. Added to the devices of previous conflicts, we have in this great world-enveloping struggle, weapons and devices new either in themselves or in their application. First among these perhaps is the aeroplane, with its revolution of strategy and tactics. We see in the modern war plane the result of aerodynamical research and developments in metallurgy and petroleum chemistry.

We know that there are radio devices which reach many miles out to sea to detect aeroplanes and ships, devices which may very well usher in a new era of radio application once peace releases them from their essential war work. We know that rockets in various forms are finding fighting applications, and we can guess that there is much more experimentation to be done.

There are new defensive weapons extensively used for the first time in this War about which we may talk freely; such weapons as those used in medicine: vaccines against diseases that hitherto were uncontrollable, the array of sulpha drugs effective against some of the great killers of war and peace, and improved methods of sanitation and prevention which, although unspectacular, serve an essential role. It is altogether possible that this will be the first war in which wounds born of battle will take a larger percentage of human toll than disease and pestilence. If we do escape a great plague, it will be a triumph for our fighters against disease—with considerable credit to the omnipresent factor of fate.

On the production front one of the great problems has been the supply of raw materials. Scientific workers and engineers, as well as industrialists, have had to do some violent readjusting of viewpoints in worrying about supplies. In the transition from an economy of plenty and oversupply to a regime of scarcity and priorities, there has been ample opportunity for high ingenuity and for realization upon many seemingly wild goose chases of the research laboratories.

Almost every day we hear of some new achievement in producing a new material for an old use or a new use for an old material. There is a new kind of glass that replaces cork as the buoyant material in life preservers—glass that is puffed up like bread dough and looks like a cinder block. Noble silver goes to work and carries electricity more efficiently than copper and is substituted for tin in solder. The normal array of alloy steels is simplified to meet the emergency situation and scarce alloying ingredients are conserved.

There is in process a revolution in food preservation that may well rival the introduction of canning that came of the Napoleonic wars. This grows out of the shortage in shipping space for overseas shipments, the lack of tin for food cans, and the rise of the quick freezing processes. Dehydration of foods of all sorts—meats, vegetables, milk—is rapidly becoming a widespread standard practice that will undoubtedly persist after the War. Plastic coatings serve in place of tin on food cans. Glass jars come into wider use.

These are random samples of some of the things that are happening in industry under the influence of the War. Some such things are born of the necessity and impetus of the War, but it should be kept in mind that war itself is a waster and despoiler in science and engineering as in almost all other things. Under the white-hot urgency of physical struggle certain developments are accelerated, but the creative beginnings usually will be found to date back to the more reasoned days of peace.

---

* Based on an address delivered before the Institute of Public Affairs, University of Virginia, on July 7.

To advise is about as far as men of science and engineers can go in actually fighting the War with their new weapons. The Fighting Services must use tools furnished them. Men of science can advise with some vigour and emphasis. Secrecy is necessary, of course, to keep the enemy from knowing what is being done. But secrecy can hide inaction as well as surprising, aggressive preparation. As with production and military action, the great problem is getting there first with the most and newest, and of meeting any new scientific weapon that the enemy might spring on us with an antidote within the minimum of time. The classic example of applying the antidote in this War was the neutralizing of the magnetic mines of the Germans by the degaussing belts for ships developed in Great Britain.

The 'mental front' ranks in importance with the fighting fronts in this War. It is neglected or handled piecemeal by this and that agency because it is shapeless, permeating battle lines that exist everywhere—in the United Nations and in the occupied and enemy countries. This mental front is within each of us. It is called morale or propaganda or the war of nerves. It is full of complexities and intangibles. It provides at once the greatest drive toward victory and the speediest retreat toward subjection. It is what makes the Russians—women and children as well as men—fight in the streets and scorch the earth. It is what immobilizes and makes uninterested non-combatants out of the peoples of some countries when invaders are at their front doors. The mental front is concerned with human motivation and mass emotions. It is the great neglected area in the War because it is not made of steel or tramping men.

Because of the nature of what they work with, psychologists and psychiatrists have great difficulty in forming and maintaining the lines along which they fight effectively. In part not enough is known about why human beings do things or do not do things, why they are willing to die or why they want to run away, either in ordinary life or in war. Much more is known than is being used, although more psychologists are used in this war effort than in any other. Experts in diplomacy, economic warfare and public opinion work as artists rather than scientists. Joint efforts by artists and scientists are sometimes difficult to arrange, but when accomplished often bring worthwhile results.

As science fights the war, it is also fighting for the peace to come. If this is not the case, the peace to come will be but an armistice breeding new wars. The design of the world organization to come must be on our drawing boards as our troops fight if we are to reconstruct the world in the shape we wish. More than swift, time-annihilating aeroplanes will be necessary to bind the world together in a new democratic order.

Many of the things happening in these crowded crucial months are winning the peace at home and conducting "the people's revolution' as Mr. Henry Wallace, vice-president of the United States, has called it. To build a just, charitable and enduring peace, he has said, inspires production to the limit, transportation as rapidly as possible to the field of battle, and fighting "with all that is in us". In fighting the War, science paves the way for peace that must come. As we fight for a sane and livable world, we can be inspired by Mr. Wallace's declaration: "Modern science, when devoted wholeheartedly to the general welfare, has in it potentialities of which we do not yet dream."

THE IMPACT OF SCIENCE ON AGRICULTURE

By Sir JOHN RUSSELL, F.R.S.

IN spite of considerable diversity, agricultural systems in the pre-scientific days usually possessed two features in common: they aimed first and foremost at providing complete subsistence for the community, money crops being a subordinate consideration; and they included measures for conserving the productiveness of the land, either by the so-called fallowing, or by letting the land revert to the wild state, or by some other device. Although these systems had a low level of productiveness they provided food for indefinitely long periods of time, and in addition possessed certain social advantages. In the system followed in Great Britain, around the Baltic, in Northern India and elsewhere, the land was divided into strips which were shared out among the participants for the purposes of ensuring equitable distribution of good and bad land. The whole complex of peasant life developed some creative art which showed itself in a love of colour, folk music and dancing, embroidery, wood carving, pottery, iron work and other peasant arts and crafts.

Unfortunately, the strip system of farming was incapable of improvement by scientific means, and as soon as the peasants insisted on a higher standard of living it had to go. The method of change varied in different countries: Russia adopted one way and Poland another. Instead of scattered strips the agricultural holding was brought into one self-contained unit. Here science was able to play its part. Unfortunately, as science came in so the peasants' arts and crafts, the colour, the singing and the dancing got somehow crowded out; they ceased to be spontaneous peasant activities and are becoming only museum pieces. It would be a great advantage to the countryside if, somehow, this apparent antagonism could be overcome.

In Great Britain the change to unified holdings had been made before the scientific era and so we were able at once to introduce science into our agriculture. It led to great improvements and in the 1860's and 1870's our farming superiority was widely admitted. Then came a remarkable sequence of events illustrating the difficulty of anything less than 'total' application of science to agriculture. The prairies of North America were gradually being opened up for settlement. The development of implement design made cereal cultivation possible, while plant selection and breeding—then only in their early stages—provided suitable varieties. Transport and business agencies arranged to take and pay for the produce. A very cheap agricultural system was worked out, and the operations were on so large a scale that considerable economies were possible with the result that wheat was put on British markets at prices below those at which our farmers could grow it. Similar developments occurred in the production of butter, cheese and meat, mitigated somewhat in the latter case by the fact that British produce always had a superior quality and so had some preference in the market. Our farmers could not compete, and British agriculture fell in the 1890's to a very low level. Then a more comprehensive application of science was attempted which was gradually directed to an increase in the output per man-hour, so allowing a higher rate of wage sufficient to keep some of the men on the land. This effort was so far successful that before the War our output per man-hour was higher in money value than in any country in Europe. It proved very difficult, however, to combine this high output per man with high output per acre: indeed there appeared to be some sort of inverse relation between them. Our output per acre was considerably lower than in the smaller Western European countries of small holdings, and our agriculture remained solvent only by reducing the numbers of paid workers: in England and Wales the fall was from 803,000 in 1925 to 593,000 in 1937–38.

The increased efficiency of the worker rather more than counterbalanced the fall in numbers, so that the gross value of the output rose somewhat even after allowing for differences in price.

Meanwhile a striking change had come over large sections of the prairie regions, the development of which had been the cause of so much trouble to British agriculturists. The system of agriculture proved destructive of the soil texture, the original crumb structure broke down, the soil changed to dust and in the high winds blew away. Soil erosion took place on a gigantic scale, and vast areas fell out of cultivation, some never to come back into agricultural use so far as we can see. The United States suffered most and led the way in the search for causes and remedies. It was shown that mixed farming, with alternations of grass and arable husbandry, was the surest way of preventing erosion and the best curative treatment for land not yet ruined beyond repair. But this meant a complete change in the commercial arrangements, and a reversion to the old principles, which included farming for subsistence, and the recognition of responsibility for the conservation of the soil. Far-reaching social changes are likely to result.

A somewhat different problem arose in tropical Africa and parts of India. The climate favoured the production of certain commodities of high commercial value, such as oil, fibre, tea, coffee, etc. The large supply of very cheap native labour ensured cheap production. So a plantation industry was developed and proved highly susceptible to scientific treatment; striking developments occurred. Then, however, arose certain difficulties. These new crops, helped by the aid of science, pushed out the native food crops; the subsistence agriculture gave way before plantation cropping, and the natives received pay for their work but not food. This substitution of money for food led to social difficulties, unrest, malnutrition, etc. Further, a change in the market requirements might render the produce of a whole region more or less superfluous thereby causing great financial loss: the history of sugar-cane in the West Indies is an example. In short, the intense specialization which followed the too exclusive emphasis on efficiency of production had two grave defects: it lacked the permanency of the older system and it did not adequately provide for the needs of the community.

During the past thirty years a great change has come over our ideas of administration, and it is now recognized that subsistence farming must be fully developed so as to ensure abundance of suitable food for the home population. This is necessitating a much broader utilization of science than in the earlier days.

Even in regions of the world where plantation cropping was not practised, the limited scientific intervention first attempted led to unexpected and undesirable results. The efficient medical and veterinary services greatly reduced the incidence of human and animal disease and so curtailed an important check on the population: the numbers of men and of animals increased and put great pressure on the land. The old system of shifting cultivation which had allowed of recuperation of fertility could no longer function: soil deterioration and in many cases soil erosion set in and a crop of troubles—social and technical—arose. These have necessitated great schemes of investigation. The general result is as before the need for a more varied type of farming, making more use of grass and leguminous crops and taking other steps to ensure soil conservation; also a larger but better organized production of crops for human and animal food; this of course involves collaboration with the veterinary and the medical staffs so as to ensure that the right foods are grown.

The War has imposed upon us in Great Britain the necessity for finding some solution of the very difficult technical problem of combining high output per acre with high output per man. The fundamental difficulty is the slowness of agricultural production, which science seems powerless to hasten. In spite of a hundred years of agricultural science crops still take as long to grow as ever they did; further, a lamb still takes five months in getting born and a calf takes nine months or more: all the big vital processes are in the main outside our control. Many of them are very dependent on season. Crops and animals are rarely ready for sale in less than 15 or 18 months after expenditure on them has begun, and as it is impossible to forecast prices for so long farmers are bound to play for 'safety first'. So it comes about that well-recognized improvements cannot be adopted because of the uncertainty whether the prices ultimately obtained will justify them. Probably there is no greater cause of frustration of agricultural science than this uncertainty about prices of produce.

In war-time this difficulty disappears and farming is virtually run on contracts, like other businesses. Prices and wages are fixed, and farmers know exactly where they are and exactly how far they can go in adopting improved methods. So in spite of almost unparalleled difficulties the output per acre now seems to be rising without any corresponding diminution in the output per man. On all grounds it is essential that British agriculture should continue to function effectively after the War. It will be needed for three purposes: (1) to help in solving the difficult social problems that will certainly arise: standards of population, national nutrition, unemployment, etc.; (2) to add to the national wealth and provide food for the community; (3) to remain as an effective protection when next a military adventurer starts a war in Central Europe.

The great need after the War will be for careful planning as to what exactly agriculture in Great Britain is wanted to do. Is it to slacken down considerably to allow of heavy imports of food for the benefit of shipping and commerce, or is it to produce as much as possible? Some sort of compromise will probably be reached. If the imports of food continued to be organized centrally it should be possible to allocate the various items among the different producing countries, giving a certain share to the home farmer at a price which enables him to pay the statutory wages without having continually to reduce the number of workers. So the difficult problem of combining high output per man with high output per acre can be solved. As an insurance against starvation in the next war it will be imperative to maintain a certain level of agricultural production.

A planned agriculture would allow of the comprehensive application of science, anything short of which may, as we have seen, have unexpectedly bad results. But the planning must not destroy the individual initiative that still remains one of the most potent factors of success in agriculture.

THE FULMAR IN THE BRITISH ISLES

By SETON GORDON, C.B.E.

THE results of the investigations into the distribution of the fulmar in the British Isles which the British Trust for Ornithology undertook during 1934–39 were published as a paper in the November issue of the *Journal of Animal Ecology*, 1941 (Cambridge University Press) entitled "The Breeding, Distribution, History and Population of the Fulmar (*Fulmarus glacialis*) in the British Isles", by James Fisher and George Waterston. The report was completed by Mr. Fisher as Mr. Waterston, now a prisoner of war in Germany, handed over his share of the work to Mr. Fisher in 1938. No one interested in the fulmar should fail to read this publication, which is one of the most interesting ornithological papers of recent years.

The spread of the fulmar, an attractive ocean bird with powerful flight that is deceptive because of its grace and apparent aimlessness, is one of the most remarkable features of British bird-life during recent decades. Until the year 1877, the fulmar bred only on the St. Kilda group of islands, which rise from the bed of the Atlantic more than one hundred miles west of the Scottish mainland. Since 1877 it has founded, up and down the coasts of Britain and Eire, no fewer than 208 colonies, in which there are estimated to be some 40,500 breeding pairs. Since the fulmar lays only one egg in the course of a season, this increase is the more remarkable.

St. Kilda has now been deserted by its human inhabitants, who were accustomed to snare the adult fulmars for oil (which they used for lighting) and food; and to take the young in the downy stage for food; and presumably, therefore, the great St. Kilda colony must now be increasing each year. But the spread of the fulmar was already taking place when the St. Kildans continued to take the fulmars for their needs, although Mr. Fisher's estimate of the number of young fulmars killed on St. Kilda in 1929 exceeds, by almost two thousand, Mr. Neil Ferguson's estimate given me of four thousand young birds taken that year.

It is not, I think, disputed that a considerable proportion of the newly founded colonies must have come from St. Kilda stock, but it seems to me probable that birds which overflowed southward from the great colonies on Iceland and the Faroe Islands have contributed to the increase. Surely, by the way, it is more likely that the Isle of Skye fulmars (p. 229) are an offshoot of the considerable colony on the Shiant Islands, twelve miles to the north, rather than arrivals from more southerly latitudes as suggested. Regarding the St. Kilda fulmars, Neil Ferguson, a St. Kilda man now living on the Scottish mainland, is of opinion that their spread eastwards was due, partly at all events, to their habit of following in thousands the whales that were towed from St. Kilda waters to the whaling station in Harris. This is a possibility which must not be lost sight of in seeking for the reason of the spreading, for we are told (p. 258) that fulmars first bred on Foula in 1878 when a whale was being cut up there.

The fulmar is primarily a bird of the Arctic and my memory of it in Spitsbergen is of a mountain-nesting rather than a coast-nesting species. In Britain, too, the fulmar has now founded several inland colonies. One of them, on an isolated basaltic rock on the golf course at Bamburgh in Northumberland, has, I am told, been forsaken during the present season of 1942. At this colony during a January day of easterly storm I recall watching the fulmars flying high to a considerable distance inland from that inland cliff.

The enemies of the fulmar are indeed few, but Mr. Fisher is perhaps on doubtful ground when he makes the statement that in Spitsbergen "there is no proof that the Arctic fox ever tackles the fulmar". In "Spitsbergen Papers", vol. 1, p. 330, a short account is given of a fulmar colony on a cliff amid the inland ice of Spitsbergen and of the fox tracks in the vicinity, the inference being that the foxes were preying on the fulmars, and again on p. 333 "we were rewarded by the sight of an Arctic fox making its way at great speed towards Fulmar Cliff". No definite proof, perhaps, but I have little doubt that the Arctic fox preys upon young fulmars when it has the opportunity.

In Scotland great black-backed gulls take fulmar nestlings as food for their own young. In July 1937, on the island of Hoy, I disturbed, beside a freshwater loch, a large great black-backed colony. One of the young gulls when alarmed disgorged a complete young fulmar which it must have swallowed only a few minutes before. The neighbouring cliffs on which the fulmars were nesting had not been disturbed that day through human agency, and the inference therefore is that the parent gull must either have driven the parent fulmar from its young, or must have come upon the young one unattended. When young fulmars disappear (as they often do) from a colony, I suspect that it is the work of the great black-backed gull.

Mr. Fisher has found that the breeding colonies of fulmars arrive earlier at their rocks than the birds which are founding colonies but have not actually bred. But the small Bamburgh colony, even when that colony was in process of being founded, arrived at their inland rock so early as the end of December or beginning of January, whereas at their breeding colony in the north of Skye the birds have not been noted on the ledges before February. Perhaps the fact that the two colonies are on opposite coasts of Britain may account for this difference in the times of arrival, but it is nevertheless worth recording.

Mr. Fisher's paper is full of interesting information. Who, for example, was aware that fulmars have been on occasion shot with young peduncled barnacles growing upon the feathers of their under parts (p. 256)? Or, that a fisherman's minnow bait was taken by a fulmar on fresh water 400 miles from the sea (p. 257)? One would have liked to have been told more about that remarkable occurrence.

It is pointed out that the nesting site of the fulmar is rather different from the sites of other cliff-nesting birds, for it is usually a steep slope of 60° or more (pp. 248–49) and not a true cliff. Neil Ferguson of St. Kilda in a letter to me apropos of this writes: "I am sure the sheep on St. Kilda are now disturbing a lot of fulmars. At the time of their laying we used, as long as we lived on the island, to fence the sheep off the easiest places where they would 'spoil the fulmars' as we used to say, and used to repair the fence each season before the laying time."

On p. 249 some unusual nesting sites of the fulmar are recorded. On North Ronaldshay the species was nesting on ruined buildings in 1934, and on inhabited dwellings in 1937; on Sanda, an isle of the Orkney group, it nests on the ground among Arctic terns.

Several instances are on record of a fulmar attacking a herring gull, but the species as a rule seems to be harmlessly disposed towards its neighbours. Yet there are a number of reports to the authors of the paper that it causes other sea birds to leave the sites which it occupies.

OBITUARIES

Prof. L. Roule

PROF. LOUIS ROULE, whose death has recently been reported, was the fifth occupant of the Chaire de Zoologie (Reptiles et Poissons) at the Muséum National d'Histoire Naturelle of Paris, a chair which, as its present occupier, Prof. Pellegrin, has remarked, seems to confer the gift of longevity on its holder. Louis Roule was born in Marseilles in 1861 and studied in the school of medicine in his native town.

Prof. Roule's early zoological work was on worms and tunicates, and his doctorate, gained in 1884, was awarded for a thesis on the Ascidians of the coast of Provence. He became professor at the University of Toulouse in 1892 at the age of thirty, his duties including the direction of the station of pisciculture and hydrobiology associated with the University. It is here that the origin of Roule's interest in fishes is to be found; that he never lost interest in the economic aspect of ichthyology is evidenced by the publication in 1914 of his "Traité de pisciculture et de pêche", and the devotion of one of the ten volumes of his "Les Poissons et le Monde vivant des Eaux" to the same subject.

Nevertheless, during his tenure of the Museum chair, to which Roule succeeded in 1910, it was largely with those fishes most remote from man's practical interests that his original works were concerned. He produced important reports on the fishes collected by the French Antarctic Expedition led by Commandant Charcot, on oceanic fishes and their larvæ collected by Prince Albert I of Monaco, and on larval and adult deep-sea eels collected by the Danish oceanographical expeditions led by Johannes Schmidt. The handsome volumes published at Monaco were enhanced by the artistic collaboration of Fernand Angel, who also illustrated the work on deep-sea eels (done in collaboration with Leon Bertin) and many of Roule's smaller publications.

The strange forms and peculiar conditions of life of the fishes that dwell poised far below the broad surface of the ocean and as far above its deep floor never fail to grip the imagination of any zoologist fortunate enough to handle them. Roule was fond of generalizations, and his conception of some of the most aberrant of the bathypelagic fishes as "monstres normalisés" was characteristic. One of the ten volumes of the popular work referred to above was devoted to abyssal fishes, and another (which was translated into English) to the migrations of fishes, a subject in which he was particularly interested. The philosophical vein in all ten volumes, and particularly in the last, allows one to suppose that he offered this book, not merely as a by-product of his scientific life, but also as a summing up of his experiences, the rounding off of a satisfying career.

E. TREWAVAS.

Prof. J. H. Salter

WE regret to record the death of Prof. J. H. Salter on August 5 at the age of eighty-one. John Henry Salter was born in Westleton, Suffolk, on June 5, 1862. In 1869 his father died, and the family moved first to Woodbridge, and then to Scarborough. Dr. Salter attended Ackworth School and afterwards became an apprentice master at the school and studied at Flounders College. He graduated B.Sc. London, and taught at various schools during 1881–88. He then proceeded to Dalton Hall, Manchester, to read botany under Prof. Williamson and Mr. Hick at Owens College. In 1891 he demonstrated at University College, London, for a short time and was later appointed as the first professor of botany at Aberystwyth, under Principal T. F. Roberts. Obtaining a year's leave of absence in 1896, he went to Bonn and worked under Strasburger. He was replaced at Aberystwyth during this time by Keeble (later, Sir Frederick Keeble).

In later years Dr. Salter often spoke with pleasure of his time at Bonn, where he formed one of a group which included Harper, Swingle, Fairchild and Osterhout, as well as Schimper and V. H. Blackman. Harper, Swingle and Fairchild were studying the dividing nucleus and the spindle, Schimper was already interested in plant-geography, and Dr. Salter was investigating the connexion between pyrenoids and starch grains. His drawings were beautifully executed in water colours, and were presented by him to the Botany Department of the University College of Wales, Aberystwyth, a week before his death. During the time that Dr. Salter worked under Strasburger, he learned from him the method of preparing herbarium sheets which he used and developed for the rest of his life. The plants were pressed between layers of cotton wool, each overlapping leaf was separated by a slip of drying paper, and the finished specimens showed all the care of the master hand. He specialized in Salix and Mentha, as well as collecting a large general herbarium, which he gave to the National Museum of Wales, Cardiff, a few months ago.

In 1897 he returned to Germany to work with Meyer at Marburg on the interrelationship between the algal and fungal components of lichens. He was convinced that the fungus obtained food from the alga, and his drawings, executed with meticulous care, form part of his recent gift to the University of Wales, Aberystwyth.

He married Adah S. Freeman of Birmingham in 1899. In 1908, he resigned from the chair at Aberystwyth, on account of a breakdown in his wife's health, and the family moved first to the Canary Islands, and then to the south of France. These countries gave wide scope for his interests and he added the record of several new species to the flora of the Canary Islands, as well as continuing his studies in conchology, ornithology and entomology.

The family returned to England in 1916 and, after his wife's death in Dorsetshire, he returned to Aberystwyth in 1923 and settled at Llanbadarn Fawr. During the succeeding years he walked for miles among the mountains and vales of the Aberystwyth district and his wide knowledge of the flora was partly collected together in "The Flowering Plants and Ferns of Cardiganshire" which he wrote in 1935. His knowledge of bird life was very considerable, and he was instrumental in initiating the movement for the preservation of the Welsh kite in the Towy valley. He also made a collection of insects which is to be given to the National Museum of Wales, Cardiff.

Since his return to Wales, Dr. Salter has taken a keen interest in his garden, where he has kept records of the flowering periods of some six hundred plants. From the age of seven until the day before his death he kept a natural history diary, which is full of information on birds and plants. The volumes, beautifully written in his neat script, are to be housed in the National Library of Wales.

Dr. Salter was a member of the Society of Friends and a man of the highest principles. He was quiet and reserved in manner, but his knowledge was always freely at the disposal of those who sought it. The fragrance of flowers, the first seasonal appearance of a plant or a bird gave him profound pleasure. No trouble was too great for him if information was desired on a subject with which he was familiar. His tall spare figure will be greatly missed from the Aberystwyth district, for he walked easily, and regularly took a twenty-five mile walk until quite recently.

His passing means that many records will inevitably cease to be collected, for he devoted his whole time to work; it means that many of us will no longer have a fount of wide information generously at our disposal; and it means also that we shall be denied the privilege of his pleasure when an interesting plant is found. He was a true man of science, a seeker after truth in every sense of the word. It has been a source of deep regret to his friends that the last few months have demanded from him inactivity and suffering.

He was laid to rest at Llanbadarn Church on August 8. He is survived by two sons, one of whom is in Canada. As scientific workers we share with them some of the privileges of having known and learned from him. LILY NEWTON.

Mr. T. Harris

MR. T. HARRIS, who has recently died, joined the Research Department, Woolwich, in January 1921 at a time when the importance of the scientific approach to problems of war and defence was beginning to be realized. He became a member of the Ballistics Branch and immediately began experimental work of a fundamental character, to which he brought with enthusiasm his wide knowledge of physics and his skill as an investigator.

The policy in those early days was to build for the future, and it was wisely decided that long-term researches should be undertaken to lay sure foundations for further development. Most of Harris's energies were devoted to such work, and in the course of time he brought to fruition several of these projects about which, because of necessary secrecy, it is impossible to give much detail. It may, however, perhaps be permitted to mention the following items which he either initiated or whose development was directed by him: muzzle vibrations of rifles; temperature of combustion of propellants; development of methods of photography of bullets in flight, both by single and multiple-spark photography; recoil problems—muzzle and chamber brakes; general internal ballistics of small arms. He was responsible for developments and improvements which have been embodied in weapons in use in the present War.

Harris's methods were essentially sound—careful, meticulous consideration of all aspects of the problem, never rushing to conclusions, and making sure of each step before proceeding further, and it should be said that his mathematical knowledge was considerable and was used with skill to keep theory and experiment in close touch.

The outbreak of war brought heavy demands on his strength and when he and his work were moved from Woolwich in September 1940 he was already a sick man. He never complained and gave unstintedly of his best to ensure the continuation of the investigations, but it was clear that the effort was costing him dear. He lived long enough to see things going satisfactorily at the new station, but a bad breakdown in July 1941 kept him away from work for about six months, and, although he struggled back for a few days in January 1942, it was apparent to all that the end was near. He inspired respect and affection in all his colleagues, and, to the writer of this notice in particular, he was a close and loyal friend, ungrudging in advice and help at a very difficult time. The country and the national war effort are the poorer by his death. C. A. C.

Dr. Arnold Berliner

IN connexion with the obituary notice of Dr. Arnold Berliner (NATURE of September 5, p. 284), Mr. F. I. G. Rawlins writes: In the summer of 1928, the University of Berlin gave an *Abendessen* to graduate students attending the *Ferienkurs* in theoretical physics. Prof. von Laue was host, and I sat next to Arnold Berliner. His conversation was brilliant, over a wide range of topics, and his enthusiasm for straightforward scientific literature unbounded. A few years before he (with Karl Scheel) had produced the monumental "Physikalisches Handwörterbuch", in which I ventured to point out a few (obvious) omissions. He replied at once—"I prepare a new edition, and I promise that there shall be no gaps". Most of the evening, he continued to discuss everything conceivable, but not without betraying some strange—and even violent—likes and dislikes, doubtless the outlet for the "artistic temperament" which filled his whole being. He stood four-square for a culture altogether too broad and too magnanimous ever to suffer complete eclipse.

WE regret to announce the following deaths:

Prof. L. Aschoff, professor of pathological anatomy in the University of Freiburg im Breisgau, aged seventy-five.

Dr. S. G. Barker, O.B.E., scientific adviser to the Indian Jute Mills Association, on August 28, aged fifty-five.

Dr. H. C. Lawrence, formerly of the Imperial Forestry Service, Burma, on August 25, aged sixty-seven.

Mr. P. A. Mytton, O.B.E., chief livestock officer for England and Wales, Ministry of Agriculture, on September 3, aged sixty-one.

Mr. Bernard Neville, formerly physics master at William Ellis School, aged fifty-five.

NEWS and VIEWS

Imperial College of Science and Technology: New Rector

PROF. R. V. SOUTHWELL, who has been appointed rector of the Imperial College of Science and Technology in succession to Sir Henry Tizard, who was recently elected president of Magdalen College, Oxford (see NATURE of August 1, p. 148), has behind him a distinguished career in the field of engineering science, starting with the award of a fellowship of Trinity College, Cambridge. At the outbreak of the War of 1914–18, Prof. Southwell had already made a name for himself as a research worker in the theory of elasticity, and this subject has remained his strongest interest in academic life. In the last few years he has made available a powerful method of solving problems otherwise intractable, by a system of successive approximations. Problems involving strains of materials or motions of fluid come within its scope, and solutions are now prominently identified with the Engineering School at Oxford.

In his wider scientific activities, Prof. Southwell has been intimately connected with aeronautical developments; during the War of 1914–18 he interested himself actively in the construction of airships before taking executive control of the Aerodynamics Department of the Royal Aircraft Establishment and its research into the characteristics of heavier-than-air craft. In the reconstruction period, Prof. Southwell transferred to the National Physical Laboratory as superintendent of the Aerodynamics Department and has since maintained his contact through his membership of the Aeronautical Research Committee; after five years as superintendent he returned to Cambridge as a University lecturer in mathematics, and a little later became professor of engineering science in the University of Oxford.

Besides his assistance to aeronautics, Prof. Southwell has aided other Government departments, such as the Ministry of Home Security and the Department of Scientific and Industrial Research. He has represented Great Britain on international committees, notably one on applied mathematics founded after the War of 1914–18 to bring former enemies into renewed scientific contact. His ability has been recognized by degrees conferred, and his outstanding value to engineering science by election to fellowship of the Royal Society in 1925. No doubt Prof. Southwell will receive a warm welcome at the Imperial College and will be a valuable asset to the University of London.

Science and the War Effort

AT a meeting of the Parliamentary and Scientific Committee held at the House of Commons on September 9, the recent appointment of three full-time scientific advisers to the Ministry of Production was considered and the following resolution was passed: "This committee, while welcoming the appointment of three full-time scientific advisers to the staff of the Ministry of Production in so far as it establishes the nucleus of a central scientific and technical board, regrets that their field of activity is apparently to be limited to the sphere of production and does not include the scientific and technical activities of the service Departments or the other Ministries outside the strict field of production. An extension of its functions is needed to ensure that all scientific considerations are co-ordinated and given full weight over the whole field of the national effort. The committee considers, therefore, that in order to cover this wider field, scientific advisers should have direct access to the War Cabinet and that accordingly the Lord Privy Seal should exercise his supervisory functions over the new body directly on behalf of the War Cabinet."

It was also announced that 126 members have now added their names to the motion on the Order Paper, which suggests that "present circumstances require the early establishment of a whole-time Central Scientific and Technical Board to co-ordinate research and developments in relation to the war effort."

A Promise to Youth

AT a meeting on September 3 of an international assembly of students made up of delegates from all the United Nations, President Roosevelt gave a pledge for the future to the youth of the world—to those who must bear the brunt of the physical warfare and who will shape the new world. He referred to the glorification of youth in which the Axis Powers have always indulged; so far from their being the real champions of youth, it is now seen they have nothing to offer save death. "On the other hand", he said, "the cause of the United Nations is the cause of youth itself." The thoughts of many are concerned with interrupted education and careers and the postponement of opportunities in life; but as, under the stress of war, the American Government has accepted the broad responsibility of seeing that suitable work shall be provided for its citizens, so in days to come that responsibility will be continued. Victory is essential, but is not enough; we must ensure the 'four freedoms' for the generations to come, and it will require "bold vision, intelligent planning, and hard work". This applies equally to all the United Nations, and involves a step of historic importance; for it means that the needs of humanity have brought together the cultures of the Americas, Asia and Europe to form for the first time a world civilization. The principles set out in the 'four freedoms' and in the Atlantic Charter as a whole provide for a world in which all may live in freedom and equity, and without fear of war. They will not be easily established, even when the War is won, but the mistakes of the aftermath of the War of 1914–18 will not be repeated. Through these principles we have the possibility of reaching the highest goals that mankind has ever imagined.

Reservation of Students in the United States

DEFERMENT of calling up for service in the American fighting forces is recommended in an *Occupational Bulletin* circulated by the Selective Service Organisation for students in training for certain sciences as well as for scientific men now engaged in critical war research work. It applies to the sciences and specialized fields certified by the National Roster of Scientific Personnel as requiring long periods of training and as being work for which the necessary man-power does not already exist to meet war production and activities essential to the war effort. They are: accountants, chemists, economists, engineers (aeronautical, automobile, chemical, civil, electrical, heating, ventilating, refrigerating and air-conditioning, marine, mechanical, mining and metallurgical including mineral technologists, radio, safety and transportation), geophysicists, industrial managers, mathematicians, meteorologists, naval architects, personnel administrators, physicists, astronomers, psychologists and statisticians. Careful consideration for occupational classification should be given, the bulletin says, not only for men already engaged in these activities necessary to war production or essential to the war effort, but also to undergraduate college students in training for them if they are in their junior or senior years, or at or near the close of the sophomore year. A graduate or post-graduate student who is undertaking further studies for these scientific and specialized fields may be considered for occupational classification if, in addition to his studies, he is also acting as graduate assistant in a recognized college or university, or is doing war research which is supervised by a federal agency. After a student graduates, it is recommended that he should be given sixty days additional deferment to give him time to enter war production or other war work.

University of Durham : Chair of Child Health

THE University of Durham has received an offer from the Nuffield Provincial Hospitals Trust to provide a grant of £15,000 towards the cost of establishing a chair of child health at King's College, Newcastle-on-Tyne. The Senate and Court of the University have accepted the proposal with gratitude. Dr. J. C. Spence, lecturer on the diseases of children, has been appointed to the chair, and the Council of King's College has expressed its intention to provide him with the assistance necessary for creating a full teaching and research department. The department will provide undergraduate and post-graduate teaching in child health and the diseases of childhood, will be a centre of research, and will be at the disposal of local public health and education authorities of the region for advice and consultation in the conduct of their child welfare and school medical services.

Simplification of Musical Notation

A MODERN writer has declared that the orthodox musical notation is "in some of its elements, foolishly illogical and unnecessarily complicated" (W. R. Anderson, in "The Musical Companion", Gollancz, p. 27), and in recent correspondence in NATURE, concluding with the present issue, correspondents have suggested simplifications. Many attempts have been made to do this in the past, but have failed to gain permanence. One of the most widely advertised, which appeared some thirty years ago, was known as Naunton's National Music System, a fundamental element of which was a simplified notation without clefs, sharps or flats. The score consisted of horizontal lines drawn from the black notes of a keyboard shown vertically on the left. Thus, black lines corresponded to *black* keys and white spaces to *white* keys. The main object of this notation was to enable the average person to become a proficient pianoforte player from a score, the precise object sought by Lord Brabazon in the original letter of the correspondence published in NATURE of May 16.

The discussion which has since taken place shows that one of the principal difficulties has been the possibility of the existence, side by side, of a standard and a simplified notation. There can be no question of the scrapping of the standard notation, which indeed enjoys the almost unique distinction of universal acceptance—in fact, it is a form of international language. To make basic changes in such a universal notation would involve the scrapping of countless costly plates and stocks, while the effect upon musical organizations would be disastrous. The musician should, however, consider the needs of the weaker brethren, who have neither the aptitude nor the time to study the finer points of music, yet wish to be able to 'make music' for themselves from time to time. Would a simplified notation contribute to this end ?

Very little has been said in this correspondence about the intricate problem of playing, but it should suffice to point out that ability to read a score does not carry with it even the simplest keyboard technique ; many moderate players cannot read, while it is quite possible for a non-player to be a fairly good reader of music. In interpreting a score at the keyboard, a vocabulary of simple chords is a *sine qua non* and, to gain this, it is worth while for a beginner to experience the joy of becoming intelligently acquainted with those delightful elements of musical composition. After all, the chords will remain unchanged whatever the notation. "If the art", says Sir Hubert Parry, "is worthy of the dignity of human devotion, it is worth considering a little seriously" ("The Evolution of the Art of Music", Kegan Paul, p. 337).

Leprosy in Brazil

ACCORDING to Eunice Weaver, president of the Federation of Societies for the Welfare of Lepers (*Bol. Of. San. Panamericana*, 21, 569 ; 1942), the total amount spent by the Brazil Federal Government for Leprosy Control was 3,584,000 dollars, of which 2,336,732 were devoted to the construction and operation of leprosaria, and the rest to research and contributions to societies for assistance to lepers and their families. On December 31, 1941, there were 15,991 patients segregated in the twenty-five Brazilian leprosaria. Federal and private contributions have permitted the establishment by various relief societies of preventoria for healthy children of lepers, in which 1,200 children are now sheltered, 1,100 more being expected. The National Leprosy Service will also contribute scientifically and financially in the installation of dispensaries and the erection and enlargement of leprosaria and preventoria.

Announcements

DR. T. ROYDS, formerly director of the Kodaikanal and Madras Observatories, has been appointed professor of astronomy in the University of Istanbul.

ONE or more research scholarships will shortly be awarded by the Royal College of Surgeons of England. The scholarships will probably be of the annual value of £400 with an allowance not exceeding £100 for expenses of research, and will be for one year, in the first instance, but renewable at the discretion of the Council. Scholars may be male or female, and must hold a medical qualification registrable in the United Kingdom or a university degree. Faculties for laboratory research will be provided in the Bernhard Baron laboratories of the Royal College of Surgeons, now evacuated to Finchingfield, Essex. Further information can be obtained from the Bernhard Baron Research Professor, at Prospect House, Finchingfield, Braintree, Essex. Applications must be made before September 19.

Lactation and Reproduction on Highly Purified Diets

NAKAHARA *et al.*[1] have claimed the existence of specific lactation vitamins, factors L_1 and L_2; they state that, if these are missing from the diet, rats will reproduce but not lactate. We[2] used a diet which was unlikely to contain these factors, but failed to confirm the finding of the Japanese workers. The recent report, by Rogers *et al.*[3], of the successful rearing of two generations of mice on a highly purified diet is of obvious interest in this connexion. We therefore think it opportune to report on experiments of our own in which three generations of rats have so far been born and reared on highly purified diets.

Description of rats	Diet	No. of animals	No. of litters born and av. no. live pups born per litter*	% pups reared	No. of litters reared and av. no. pups weaned per litter	Av. weaning age (days)	Av. weaning weight (gm.)
			FOUNDATION STOCK				
(*a*) Stock colony does	Stock	8	7; 10·8	75·0	7; 6·0	21	41·2
(*b*) Stock colony does	*A*	8	8; 5·9	34·8	3; 5·3	30	29·4
			1ST GENERATION				
(*c*) Progeny of (*b*) ..	*A*	10†	10; 5·4	15·1	2; 4·0	27	39·5
(*d*) Progeny of (*b*) ..	*B*	6	6; 7·2	41·5	3; 5·7	30	32·8
			2ND GENERATION				
(*e*) Progeny of (*c*) ..	*A*	2‡	2; 8·5	0§	—	—	—
(*f*) Progeny of (*c*) ..	*B*	2‡	1; 8·0	0‖	—	—	—
(*g*) Progeny of (*d*) ..	*A*	3	3; 9·0	25·0	1; 6·0	29	26·3
(*h*) Progeny of (*d*) ..	*B*	3	3; 6·2	27·8	1; 5·0	26	28·8

* Larger litters were reduced to 8 at birth.

† Four of these animals are referred to in both of lines (*c*) and (*d*) since they produced their first litters on diet *A* (of these, two were the only ones reared on this diet) and their second litters on diet *B*.

‡ One female still to be mated.

§ One female afterwards reared, out of eight pups, one ♀, weighing 49 gm. at 33 days.

‖ One female afterwards reared, out of seven pups, two ♀♀ and one ♂, weighing 169 gm. at 44 days.

Two main experiments are in progress in each of which the foundation stock consisted of litter-mate stock colony does weaned on to the stock diet[2] or to a highly purified diet (diet *A*) consisting of sugar 60, casein (flavin-free) 20, lard 3, groundnut oil 12, salts 5 and supplemented by aneurin, riboflavin, vitamin B_6, nicotinic acid, inositol, choline, Ca-pantothenate, *p*-aminobenzoic acid, 2-methyl 1 : 4 diacetyl naphthohydroquinone, cod-liver oil and α-tocopherol, the last two being administered on different days[4]. In view of the claim[5] that it is essential to add cystine to casein diets to obtain normal lactation in the rat, some animals received the above diet supplemented with 0·2 per cent cystine (diet *B*).

The results so far obtained in one of these experiments are summarized in the accompanying table which, except where otherwise stated, only relates to the first litter of each female. In all cases the females on the experimental diets were mated with stock colony bucks.

It is evident that the lactational performance of rats receiving the purified diet was always inferior to that of females fed on the stock colony diet. No very definite conclusions can be drawn with regard to the effect of cystine on lactational performance, but the fact that a considerably larger percentage of pups was weaned on diet *B* suggests that it exerted a beneficial effect.

Notwithstanding that lactation on the experimental diets is sub-normal, members of all four subgroups of second generation females have weaned pups, so that three generations have been reared so far on highly purified diets in the absence of factors which might be said to be specifically required for lactation.

The experiments are being continued and will be fully reported elsewhere. The helpful advice given us by Dr. T. F. Macrae is gratefully acknowledged.

A Simple Method for Enzyme Concentration

A METHOD for the concentration of enzymes and other biological colloids was recently described by Guy E. Youngbourg[1]. By this method the volume of the active solution is reduced by dialysing it against a concentrated solution of dextrin. In a previous paper[2] concerning the concentration of taka-diastase it was shown that this method was impracticable for sugar-hydrolysing enzymes, owing to the diffusion of part of the dextrin into the solution. Seeking other methods of concentration, we succeeded in finding a simple procedure by dialysing against 96 per cent ethyl alcohol or acetone as the 'outside solution' (provided only that the active substance is not inactivated by them). By this procedure the volume of the active substance is rapidly reduced. A partial precipitation from the solution during concentration sometimes occurs, but does not interfere with the final result.

The alcohol or the acetone can be regained each time by redistillation and used again. By this method dialysis can be carried out at room temperature without any danger of bacterial infection because of the alcohol or acetone medium in which the dialysis is made.

No inactivation during the experiment was observed. The enzyme solution is poured into a Cellophane bag, the mouth of which is tied securely about a glass tube made of a test tube, large enough to permit the addition or removal of the solution. The Cellophane bag with its protruding glass tube is suspended within a tall beaker into which the alcohol is introduced, submerging the Cellophane bag and its contents and allowing diffusion of the water from the solution into the alcohol. For about 50 ml. of solution being concentrated we used 200 ml. alcohol. Within 3–8 hours the original volume is reduced to about one tenth. If the alcohol is changed two or three times, the time of concentration is reduced by half.

Part of the enzyme is precipitated during concentration and forms a deposit on the Cellophane. The concentrated solution is taken out by a pipette or by tearing the Cellophane, and precipitated with an equal volume of absolute alcohol or acetone. After centrifugation and washing with ether, the substance and the Cellophane coated with the active substance are dried in a desiccator over sulphuric acid.

It is possible by dialysing over a longer time to remove completely all the water of the active solution and to obtain the active substance as a precipitate on the Cellophane. After drying the Cellophane in the desiccator or in air, the substance can easily be separated from the Cellophane. If but minute quantities of enzyme were in the solution the dried Cellophane with the deposit on it can be introduced in water which dissolves the substance. We employed this procedure for the concentration of taka-diastase, pancreatin, pepsin (all from Parke Davis and Co.) and yeast extract protease, as well as in preparing papain from *Carica papaya* latex from Jericho, Palestine, for which I am indebted to the Department of Agriculture of the Palestine Government.

All the enzymes were obtained in a dry, active form. It remains still to be seen whether the method may be employed for the concentration of desmolytic enzymes as well as other biologically active substances.

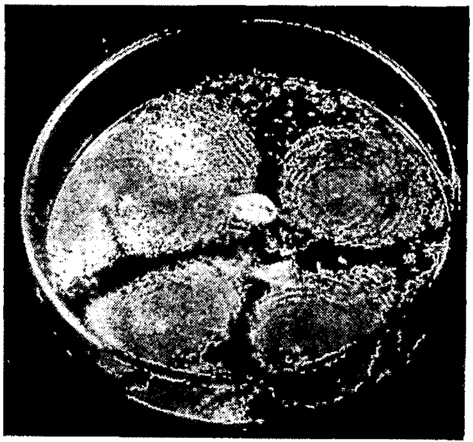
A Mucorine Parasite on Penicillia

In the course of blowing experiments on air-dried soils, by use of an adaptation of a simple type of 'spore-blower' recently described[1], a growth of Piptocephalis was obtained which proved to be parasitic on Penicillia.

This has now been in culture for more than a year. The original Penicillium from the soil, on which it was first found, has not yet been satisfactorily named, but the parasitism of the Piptocephalis on it has been fully confirmed by observation. The parasite has also been obtained in culture on a number of other unnamed Penicillia, and on the following named cultures: *Penicillium roqueforti, P. notatum* (Fleming's strain), *P. pfefferianum, P. glabrum.* It has failed to grow on *P. camemberti*, on a member of the Biverticillata Symmetrica, on several fasciated Penicillia, and on a number of common Hyphomycetes of different genera.

Among the Mucorales it has so far been obtained in growth on *Mucor mucedo* + and —, and *M. hiemalis* + and —, but has not grown on a wide range of other Mucorales. Growth on the Mucors is distinctly sparser than on the Penicillia, on which it is dense and luxuriant.



Piptocephalis sp. on Penicillium

The Piptocephalis does not correspond closely to any described species, but it is nearest to *P. Tieghemiana* Matruchot[2]. Its special interest lies in the fact that, so far as I can discover, no mucorine parasite has hitherto been reported as growing on a mould other than another member of the Mucorales. Matruchot, in 1903[3], based his view that Cunninghamella is a member of the Mucorales chiefly on its ability to act as host to *P. Tieghemiana*, which would grow only on Mucors, and in most works dealing with it the genus Piptocephalis is said to be parasitic only on the Mucorales.

The breaking down of this generalization may perhaps lessen the imaginary gap between the Mucors and the Plectomycetes, and at the same time discourage the tendency to regard mucorine parasitism in general as a phenomenon related to sex and based upon close physiological relationship.

So far as can be seen at present the ability to support this parasite cuts across the ordinary divisions of the Penicillia, and it is possible that, since the parasitism when it occurs appears to be strongly marked, and to result in a conspicuous growth of white (ageing to buff) 'conidiophores' above the host (see photograph), it might provide in some cases a useful additional character for distinguishing Penicillia.

Since this note has gone to press the Piptocephalis has been obtained in profuse growth on *Aspergillus niger*. This enlarges considerably the scope of its parasitism.

A detailed study of its morphology is now being undertaken by Miss M. P. English.

Plant Ecology of Bombed Sites

Many of the unsightly scars left by the air-raids on London are now being hidden by a carpet of vegetation. Some notes on its growth on a small bombed site in a terrace in the heart of Kensington may be of interest. A three-storied corner house with a basement area and no front garden of any kind was completely destroyed by a direct hit in September 1940, but the site and that of the adjacent damaged house was not cleared until the autumn of 1941. It was then fenced off by a wooden paling which enclosed the former stretch of pavement in front of the two houses.

At that time there was scarcely a trace of plant growth. Now the site is gay with blossom. For the past six weeks there has been quite a mass of the handsome pink rosebay (*Epilobium angustifolium*) growing 3 ft. tall, which is becoming one of the most abundant weeds of waste ground and neglected gardens in London, no doubt owing to the wide distribution of its light tufted air-borne seeds; but what is more remarkable, there are no less than twenty strong young shrubs of *Buddleia variabilis* coming up, the largest of which, growing on the site of the former pavement, are now coming into flower. One of them is already six feet high and has, in flower and bud, thirty-six heads of bloom, some of them nine inches long. The nearest possible parent plant which I have been able to trace is fully a hundred yards away.

Altogether there are twenty-two different species at present in flower on the site, belonging to ten natural orders (9 composites, 3 grasses, 3 species of Epilobium, 1 Crucifer (shepherd's purse), 1 Caryophyllaceæ (chickweed), 1 Leguminosæ (clover), 1 Plantaginaceæ, 1 Chenopodium, 1 Polygonum, 1 Loganiaceæ (Buddleia), besides thick patches of moss with fruiting capsules).

Change of Sign of the Thermal Diffusion Factor

The change of sign of the thermal diffusion factor α with composition, which Prof. S. Chapman[1] has pointed out is theoretically possible in certain conditions, has been found to occur in neon-ammonia mixtures recently examined.

In a mixture of molecules differing slightly in mass and interaction, the thermal diffusion factor α may be considered approximately as consisting of three terms. Two of these terms represent the contributions of the mass difference and of the diameter difference of the molecules; the third involves the force index and the departure of the mutual collision diameter s_{12} from the mean diameter $(s_1 + s_2)/2$. This third term, unlike the others, depends on the concentration; although small when the mass contribution and the diameter contribution are of the same order but opposite in sign, it may suffice to bring about a change of sign of α as the composition of the mixture varies. The neon-ammonia mixture is one of few in which the mass difference is small and the heavier molecule is the smaller, so that it satisfies at least the requirement that the mass and diameter contributions should be opposite in sign.

Mixtures of various composition were examined, a Clusius-Dickel column (made in Pyrex glass) being used to increase the separation due to thermal diffusion alone, as this is too small to measure by the direct method used hitherto. Since the direction of the longitudinal concentration gradient which is set up in the column is determined by the direction of the thermal diffusion transversely, and this in turn is determined by the sign of α, a change in the sign of α would appear as a change in the direction of the concentration gradient. The experimental results are shown in the figure, where the separation, that is, the difference in percentage composition at the upper and lower ends of the column is plotted for mixtures of varying composition. Between 0 and 75 per cent neon, the neon concentrates at the upper end of the column. This means that the heavier, neon, molecule diffuses up the temperature gradient—a direction of diffusion, it is believed, not hitherto observed. Above 75 per cent neon, the neon concentrates at the lower end, indicating that the sign of α is now changed.

Abnormality of Flame Gases

It is becoming increasingly recognized that flame gases (that is, the gases left behind after flame has travelled through an inflammable mixture) hold a latent energy (which may amount to as much as 20 per cent of the heat of combustion or even more), and in virtue of this an abnormal amount of dissociation obtains in them[1]. In the absence of surface, the latent energy has an exceedingly long life. It has been observed to exist *in sensibly undiminished amount* for at least 0·5 sec. Luminosity experiments indicate that it still persists even after 14 sec. (and probably much longer); and it survives the cooling of the flame gases by adiabatic expansion, for subsequent recompression restores the luminosity[2]. It seems clear that it resides in the newly formed tri-atomic molecules as an excess of intra-molecular energy held in some manner or other in very stable fashion. It was suggested that a proportion of these molecules are meta-stable molecules probably of abnormal structure[2]—a proportion which varies with the conditions obtaining during combustion, for the amount of latent energy varies with these conditions[3].

Gaydon[4], from his recent interesting investigations into the origin of the spectrum from carbon monoxide flame gases, has arrived at the conclusion that, while the newly formed carbon dioxide molecules may be of the electronically excited (tri-angular) variety, a transition to the ground state rapidly takes place, and the molecules are left in a highly vibrationally excited state. He believes that there may be a lag in the partitioning of the excess vibratory energy, and that as there is continual recombination proceeding after dissociation, an excess of vibratory energy would be maintained for a period of time which would account for the long-lived latent energy. He finds support for his view from the fact that hydrogen and water vapour decrease the latent energy in carbon monoxide combustion, and that this correlates with the well-known experiments of Garner and his colleagues, which showed that these substances greatly reduce the (infra-red) radiation from carbon monoxide explosions.

I can find no support from the radiation experiments of David and Parkinson[5] for the view that the carbon dioxide molecules in flame gases hold an excess of vibratory energy of a type which gives rise to infra-red radiation (2·8 μ and 4·4 μ); indeed, these experiments suggest that a rapid partitioning of the vibratory energy takes place, and that the amount of this energy is at all times after combustion governed by the flame gas temperature. The experiments further indicate, I think, that erroneous deductions have been drawn from Garner's experiments. The decrease in the radiation on the addition of hydrogen and water vapour would appear to result entirely from more rapid cooling. It has been shown[6] that the faster the speed of an explosion the greater the turbulence set up in the resulting flame gases, and, therefore, the more rapid the cooling. The step in Garner's radiation curves may be correlated with the sudden increase in the speed of the explosion at a critical addition of hydrogen.

Experimental work performed during the last fifteen years would appear to be more satisfactorily explained in terms of the abnormal structure hypothesis, the abnormal molecules (which in the case of carbon dioxide may be of the triangular type) reaching the ground state only when they come in contact with a surface or *when two of them possessing sufficient energy collide*. In the latter event the emission of radiation in the luminous region takes place. In this connexion it is of interest to note that flame gases with any given latent energy content emit luminous radiation with an intensity which is dependent upon the gas temperature[2].

It may be added that a latent energy exists in hydrogen and hydrocarbon flame gases as well as in carbon monoxide flame gases, and, indeed, the spectrograms of Kitagawa and Gaydon from hydrogen flame gases suggest the presence of activated water molecules[4]. Usually it is much less in the former than in the latter for reasons which have been discussed[1,7], but there is reason to suppose that it may be very large even in hydrogen flames when they are burnt at low pressure. It is of interest to note that water vapour reduces the latent energy not only in carbon monoxide flame gases but in hydrogen flame gases also[7].

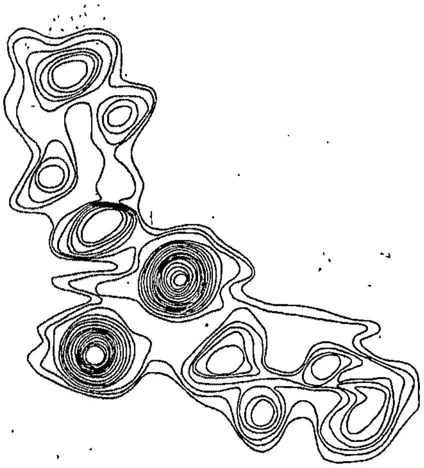
Folding of the Selenanthren Molecule

It is generally accepted that the molecule of selenanthren 
is folded about the line joining the selenium atoms, but no experimental data have so far been obtained which would give the actual value of the angle of fold, although estimates have been given[1]. It has also been suggested that the selenanthren molecule is not rigid but is flexible about the line of folding[2].



Projection of selenanthren molecule on (010) plane

In continuation of the work on the crystal structure of selenanthren already published[3], we have made a projection of the unit cell on the (010) plane. This projection was made by Fourier synthesis using photographically measured intensities of reflexion of X-rays on a monochromatic Weissenberg photograph. The appearance of the projected molecule is shown in the diagram. A single projection is of course insufficient for a complete determination of the atomic co-ordinates, but if it is assumed that the benzene rings are regular plane hexagons of side 1·41 Å.[4] the following results are obtained:

(1) The angle of fold of the selenanthren molecule about the line joining the selenium atoms is 127°.

(2) The interatomic distance carbon-selenium in the molecule is 1·96 A.

(3) The valency angle of selenium is 96°.

A small change in the assumed carbon-carbon distance in the benzene ring has little effect upon the calculated values. Thus for an assumed distance of 1·39 A. instead of 1·41 A., the three quantities become 127°, 1·97 A., 97° respectively.

A full account of the work will be published as soon as time permits.

Publication of Scientific Research carried out in Industry

ONE point bearing on Sir Lawrence Bragg's address on "Physicists after the War" (NATURE, July 18, p. 74) which should be noted is the practice of many British firms of refusing publication of research carried out by their staffs. Each year a considerable amount of scientific investigation is carried out by research workers in industry, the results of which remain quite unknown to the scientific world in general. This is generally on account of the unwillingness of industrial companies to allow their competitors to obtain any information which might be useful to them.

One obvious result of this policy is that it reduces the amount of scientific knowledge which is available. The free exchange of information is prevented, and there is a duplication of research work and a general slowing down of the progress of industry. Moreover, the quality of research is always lower the fewer and less qualified are its critics. A worker is inevitably less exact and scrupulous in a research which is written up for a probably unscientific board of directors than he would be if it were published in a technical journal; thus much so-called research carried out in industry and accepted as sound, would be more correctly appraised and acted upon if it were submitted to outside criticism through publication. On the other hand, the results of much excellent work never become known outside the particular company.

Another unfortunate effect is that the applied research worker obtains far less satisfaction from his work than his counterpart in the university, who is able to publish his results. The industrial worker realizes that his company regards his creative activity as being primarily directed towards the enrichment of shareholders, rather than towards the benefit of mankind in general. The objective of the industrial worker is thus inferior to that of the worker in pure science or medicine, and he may eventually react by treating his work merely as a means towards making a living.

The non-publication of research carried out by private enterprise seems to be far less pronounced in the United States than in Britain. In my view, the vigour and rapid progress of American technical industry can be ascribed very largely to the wealth of information which is available in the American literature of applied science. This volume of activity comes partly from the industrial research worker himself, and partly from university scientific workers who have become interested in the subject in question. The act of publication brings the most recent developments in industry to the notice of the academic worker and allows him to make his own contribution to the various problems which are opened up. There is thus a closer liaison between university and industry than has yet been achieved in Great Britain, where the two groups are often quite ignorant of developments in their respective fields.

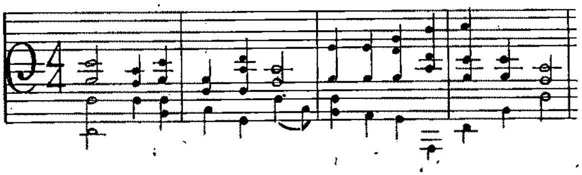
K. G. DENBIGH.

Simplification of Musical Notation

BY a slight modification of my suggested new stave[1], I have succeeded in still further increasing the ease of reading music. Following the precedent of the ancient division of the Great Stave of 11 lines, in which the middle *C* line was omitted, I suggest the omission in my new stave of the *two* lines denoting middle *C* sharp and *D* sharp and inserting these as leger lines whenever necessary. Further, to secure symmetry, the three bottom lines Bass *F* sharp to *A* sharp can also be omitted, and inserted as leger lines when required. The stave is thus reduced to 5 lines in each half—no more than in the standard notation.

The limitation of the "Bass Clef" is not likely to be found any disadvantage for two reasons: (1) The extended leger lines in sets of twos and threes present no difficulty in reading, even to the beginner; the readability of the system in this respect is another of its advantages over standard notation. (2) Examination of a wide variety of existing piano music, including hymn tunes, discloses that by far the majority of bass notes fall within the range *C* natural upwards, covered by the new curtailed stave.

Dr. Harrison's comments Nos. 4, 5 and 6[2] are most easily answered by the following example, showing four bars of Beethoven's Adagio in *B* major (5 sharps), from the "Emperor" Concerto:



The objection that this stave does not show key relationship is of diminishing importance in these days when many compositions are written 'without key', but it can obviously be met by simply stating the key above the stave wherever important key changes occur.

The above was written on August 8, but subsequently I have seen Lieut. Alan G. Smalley's letter in NATURE dated August 15. His ingenious suggestion of a 12-note stave having 6 equidistant lines and 6 spaces to the octave is fascinating, but the question whether it would be easier to read than my revised form of stave could only be settled by the 'controlled experiment' mentioned by Mr. Lloyd. Perhaps I may offer a few comments :

(1) My stave does not necessarily occupy more space. By arranging to give equal space to each semitone throughout the scale, that is, making the wider spaces one and a half times the others, the overall depth for an octave is the same as Lieut. Smalley's stave. This accurate spacing, in fact, is essential in order that all like intervals should be consistent in all keys.

(2) Experience has shown that more than five parallel equidistant lines usually become confusing to the eye, particularly in extended lengths, as on a page of music. I feel it would be difficult to read a series of chords rapidly on a six-line stave—one cannot easily avoid occasional confusion between lines 3 and 4. Also, I found a heavy line tended to catch the eye and distract attention from the music at times, so that it became a hindrance rather than a help.

(3) My stave, although primarily for keyboard music, is not unsuitable for other instruments. Since all 'naturals' are written on spaces and all sharps and flats are on lines, there is no uncertainty in reading, and in fact I find it easier to sing from than old notation.

Further, the stave obviously lends itself readily to the abolition of special clefs, since by placing the double lines above the triple lines, or vice versa, it can be made to represent any octave, with the C low or high on the stave, as desired. The 'pitch' of the stave could be easily indicated by a suitable conventional sign.

[1] NATURE, 149, 640 (June 6, 1942).

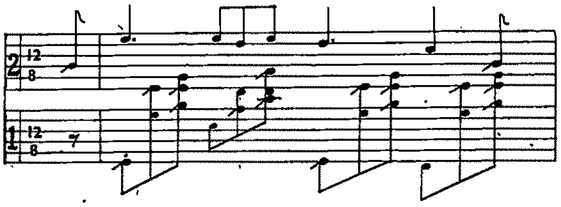
[2] NATURE, 149, 734 (June 27, 1942).

LORD BRABAZON'S appeal (NATURE, May 16, p. 554) for a simplified musical notation particularly interested me inasmuch as I have encountered all the difficulties he mentioned in learning to read music. Some time ago I developed what I considered to be an improved musical notation, but was discouraged from pursuing it by my wife, who is steeped in classical musical tradition. Lord Brabazon's comments were all I needed to get me to renew my efforts to systematize my notation.

It seems to me that the chief difficulties in the path of the musical novice arise from three causes. These are the dissimilarity of the bass and treble clefs; key signatures which, while they appear at the beginning of each bar, must be remembered thereafter; and notes written high above the treble clef, or far below the bass clef.

I propose a six-line clef, the bottom line to be *E*, and the top line the second A above it. Adjacent clefs will be separated by two spaces and a short line to be written in when the dividing *C* occurs. Instead of bass and treble signatures, the clefs will be numbered. The one which is obtained by adding a line to the bottom of the present bass clef will be 1, the one obtained by adding a line to the top of the present treble clef will be 2. The one below the bass will be the zero clef, and the one above the treble will be 3. These four clefs will more than cover a standard piano keyboard. The clefs are identical.

There will be no key signature, nor will the conventional sharp and flat signs be written in. A small tail affixed to a note will indicate an accidental. If it points up, the note is raised a semitone, if down, a flat is indicated. When the score runs above the 2-clef or below the 1-clef, the 3 or 0-clef will be written in for the required interval, and appropriately numbered.



I am submitting the opening measure of the Chopin Nocturne Opus 9, No. 2 in *E*-flat, written in the proposed notation. Inasmuch as this scheme compresses the space between the clefs, it is necessary to write notes to be played with either hand in either or both clefs. Differentiation is obtained by pointing the stems of notes to be played with the right hand up, those for the left hand down.

Brief experimentation with this notation has convinced me that it is simpler to learn than conventional music, and that sight reading is made many times easier. I have very little hope of its being adopted generally, however, for as Lord Brabazon pointed out, musicians are very jealous of their art, and seem to revel in its complexity.

A Russian-English Technical Dictionary

IN connexion with Sir John Russell's letter in NATURE of July 11, on the subject of a Russian-English Technical Dictionary, workers in the plant sciences may like to know that a comprehensive glossary of Russian botanical terms, somewhat on the lines of Artschwager and Smiley's "Dictionary of Botanical Equivalents" (Baltimore, 1921), has been in process of compilation by us for the past two years, with a view to ultimate publication. While intended primarily to cover the field of descriptive or taxonomic botany, it will include also terms from as many other branches of the science as possible, besides a number of words of not strictly botanical application but of frequent occurrence in descriptive botanical works, for the benefit of those with little knowledge of Russian. An abridged copy, in the form of a card-index, will shortly be deposited at the Science Library, and additions will be made to it as the work of extraction proceeds.

The compilers would be glad to hear of any Russian botanical (especially non-taxonomic) works, available in Great Britain, likely to yield numerous, or unusual, technical terms.

CRYSTAL STRUCTURE OF OXYHÆMOGLOBIN

By M. F. PERUTZ

Cavendish Laboratory and Molteno Institute, Cambridge

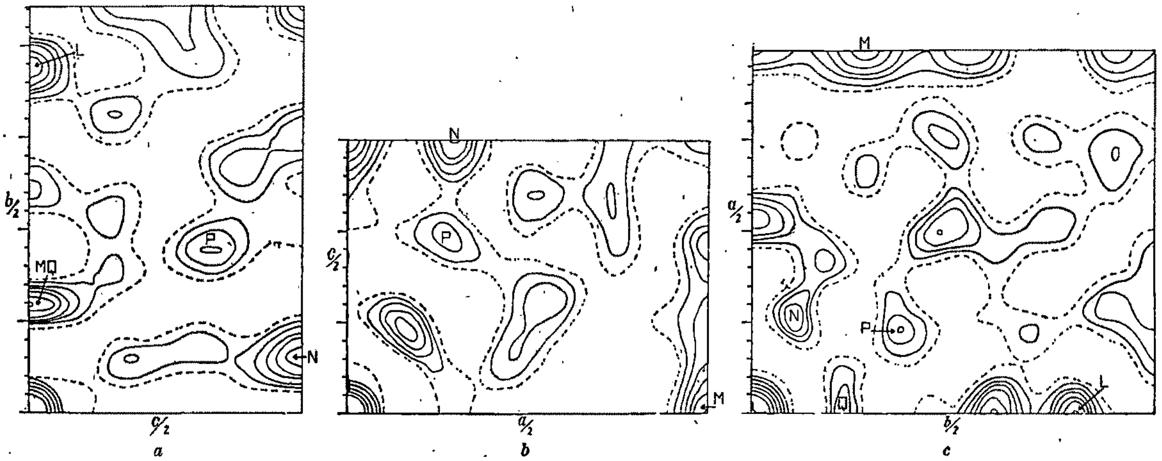
DR. E. F. HARTREE recently gave me a preparation of horse oxyhæmoglobin crystals which he had grown from 20 per cent alcoholic solution. It was found that these give good X-ray diffraction pictures both in the wet and the air-dried state, and that they promise to become an interesting subject for X-ray analysis. Though the present preliminary survey of the crystal structure has not led to any new information regarding the molecular architecture of oxyhæmoglobin, it has already given some useful hints about the way in which the molecules are arranged in the crystal.

It is well to compare the crystals of oxyhæmoglobin with those of methæmoglobin, on which work has now been in progress for some time[1,2,3]. Horse methæmoglobin crystals are monoclinic and exhibit strong birefringence and dichroism; there also exists a variety of oxyhæmoglobin crystals which is isomorphous with them and possesses the same optical properties[2,4]. It was surprising, therefore, to find the present crystals to be weakly birefringent, orthorhombic needles which appear almost isotropic when viewed along the needle axis and which show no trace of dichroism in any direction. While methæmoglobin crystals shrink visibly and violently on drying, no corresponding shrinkage of oxyhæmoglobin crystals could be detected under the microscope. On the other hand, drying affects their optical properties in an interesting manner; the optical character changes from negative to positive on drying and becomes negative again on rewetting.

Owing to the great instability of the wet crystals, all optical and X-ray measurements had to be carried out in a cold storage room at 2° C. (kindly put at my disposal by Prof. J. Gray at the Department of Zoology). Even so, the minimum exposure needed for one good X-ray photograph weakened the diffracting power of the crystals to such an extent that a second photograph from the same crystal showed only feeble blurred layer lines. In the circumstances it was not possible to determine more than the length of the needle axis, which is 64 A., as compared to 58·3 A. in the air-dried crystals. The latter are easier to handle as they are stable at room temperature and do not deteriorate much during exposure to X-rays. They give a sharp diffraction pattern with reflexions extending down to spacings of about 7–8 A. The cell dimensions are $a = 77{\cdot}6$ A., $b = 86{\cdot}8$ A., and $c = 58{\cdot}3$ A., giving a cell volume of 393,000 A³. The space group is $P\,2_1 2_1 2_1$, with four molecules in the unit cell.

The first step in the analysis of the structure of oxyhæmoglobin is to find the orientation of the four molecules with respect to the crystal axes. Now the orientation of the two hæmoglobins in the unit cell of methæmoglobin is known, and it was thought, therefore, that a clue might be found by comparing the 'vector maps' for the two different kinds of crystals. Accordingly, vector maps were prepared for the three principal crystal planes of oxyhæmoglobin (Fig. 1) and each map of this set was compared with each of the three maps which had previously been obtained from methæmoglobin. The comparison showed the peaks on the c projection of oxyhæmoglobin to be rather similar in position and shape to the peaks on the a projection of methæmoglobin, if the two projections are superimposed with the y axes in parallel. In Fig. 2 the central portions of the two projections are seen side by side, and in Fig. 3 they are superimposed. Only those parts of the two maps are shown which lie within a radius of about 20 A. from the origin, because only the intra-molecular peaks are significant for the present purpose. If we assume that there is no difference between the general molecular architecture of oxyhæmoglobin and methæmoglobin—an assumption which is reasonable both on chemical and crystallographic grounds—then the correspondence between the two maps indicates a similarity between the orientation of the hæmoglobin molecule with respect to the c plane in oxyhæmoglobin on the one hand and the a plane in methæmoglobin on the other.

The X-ray data on methæmoglobin lead us to believe that the hæmoglobin molecule is a platelet with a roughly elliptical base, that the axes of the ellipse are ∼ 48 A. and 64 A. and the thickness of the platelet is 36 A. (This view is based partly on pub-

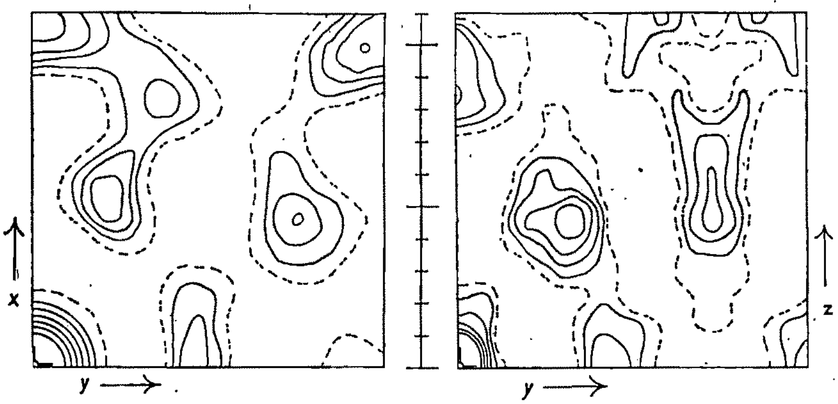


a b c

Fig. 1.

PATTERSON FOURIER PROJECTIONS OF AIR-DRIED OXYHÆMOGLOBIN. EACH PROJECTION SHOWS A QUARTER OF THE UNIT CELL. Contours are drawn at arbitrary intervals. The zero contours are dashed and negative contours omitted. The scales mark intervals of 2A. The origins are in the left-hand bottom corners.

lished data[3], partly on evidence which has come to light since.) For the purpose of describing the orientation of this platelet in the unit cell, the short and the long axes of the ellipse will be termed A and B, and an axis at right angles to the other two will be termed C. In methæmoglobin, A and B are known to lie parallel to the x and y axes respectively. The close correspondence between the two vector maps (Fig. 3) indicates that in oxyhæmoglobin B is parallel to y and C encloses an acute angle with x. The exact angle cannot be determined from the maps, because they merely show projections of the peaks the heights of which above the plane of projection are unknown. If the angle $C - x$ is, say, 30°, then the symmetry elements of the space group would require the angle to be $+ 30°$ for one pair of molecules in the unit cell and $- 30°$ for the other. Such an arrangement would account for the optical properties in a qualitative way: while in methæmoglobin the molecules all lie in line and the high birefringence and dichroism of the crystals give a true picture of the optical anisotropies of the individual hæmoglobin molecule, in oxyhæmoglobin the directions of maximum and minimum birefringence and optical absorption in the two pairs of molecules would be opposed in such a way as to compensate each other. The reversion of the sign of the birefringence on drying could be brought about by a slight change in the tilt of the molecule, namely, the angle $C - x$.



Oxyhæmoglobin Methæmoglobin

Fig. 2.

COMPARISON OF THE *c* PROJECTION OF OXYHÆMOGLOBIN WITH THE *a* PROJECTION OF METHÆMOGLOBIN. Only the central portions of the projections are shown. The Fourier summation for methæmoglobin was carried out by Dr. D. P. Riley, of Oxford.

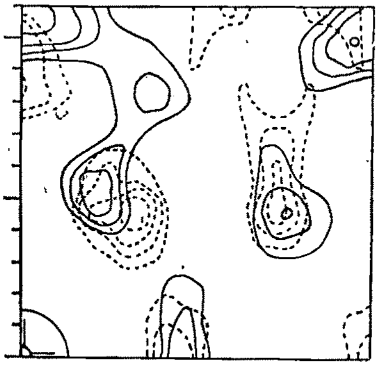


Fig. 3.

SUPERPOSITION OF THE TWO PROJECTIONS SHOWN IN FIG. 2.

The zero contours are now omitted: the full lines refer to oxyhæmoglobin and the dashed ones to methæmoglobin. In both Figs. 2 and 3 the scales mark intervals of 2 A.

The vector maps of oxyhæmoglobin are simpler in some respects than those of other proteins. Some, at least, of the peaks can be traced unambiguously in all three projections and co-ordinates assigned to them; they are marked L, M, N, etc., in Fig. 1. It is disappointing though that the maps do not provide any clues to the relative positions of the molecules in the cell. Knowledge of the three-dimensional vector structure might provide more evidence on this point. In the meantime, a structural model has been built up purely from considerations of packing, but further information is needed before it can be proved whether it is correct or not.

It is interesting to note that in dried crystals of oxyhæmoglobin, insulin[5] and chymotrypsin[2], reflexions are observed at spacings so low as 7 A., while in dried methæmoglobin[2] and lactoglobulin[6] that limit is 13 A. and 20 A. respectively. The degree of shrinkage on drying in the first group lies between 20 per cent and 30 per cent, whereas in the second it reaches 50 per cent. This shows clearly how the degree of perfection of the crystal depends on the violence of the shrinking process.

I wish to thank Dr. E. F. Hartree for providing me with the crystals, Dr. D. P. Riley for carrying out one of the Fourier summations, and Miss M. J. Boyes-Watson for preparing the drawings. I am greatly indebted to the Rockefeller Foundation for financing this research.

COUNCIL FOR SCIENTIFIC AND INDUSTRIAL RESEARCH, AUSTRALIA

ANNUAL REPORT

THE fifteenth annual report of the Council for Scientific and Industrial Research, Commonwealth of Australia, covers the year ended June 30, 1941, and includes the financial statement as well as lists of publications of the Council and of the personnel of the Council and its committees and the committees concerning work in which the Council is co-operating.

A large part of the Council's activities is now devoted to the solution of problems arising out of the War, and to assistance and advice to various Government departments and other institutions and organizations which are concerned with that effort. This applies particularly to the National Standards Laboratory, the Aeronautical Research Laboratory, the Forest Products Laboratory and the Division of Industrial Chemistry. The reference to these activities is limited to brief general statements or omitted entirely.

Plant investigations have been concerned with native or naturalized plants as alternative sources of fibre, particularly as a substitute for jute, and investigations aimed at ascertaining the difference between the fibre from various Linum (flax) strains of good type are being continued. A survey is in progress to ascertain the position with regard to domestic supplies of vegetable and farm crop seed and methods of maintaining them. Weed investigations have shown that the St. John's wort can be virtually eliminated wherever subterranean clover can be grown successfully, but spraying with chemicals has failed to control an infestation of blackberry, and the work on both nutgrass (*Cyperus rotundus*) and mintweed (*Salvia reflexa*) has indicated that chemical sprays are of no value in controlling either plant. Field experiments on the control of take-all and the root-rot of wheat have continued at three sub-stations.

The work on the chemistry of tobacco at the University of Sydney was discontinued, as well as the study of disease resistance by the Section of Genetics. Work on the yellow dwarf disease, however, has continued actively, as well as investigations on smoking quality and physiological investigations. Fruit investigations have included an extension of the experiments on wax coatings for apples, and a reorganization to co-ordinate the wider attack on this problem organized by the Division of Food Preservation. A re-examination and summary of the results of the work carried out in Tasmania on the brown-heart problem during the last five years has been made. Extended co-operation with the Tasmanian Department of Agriculture in experiments, particularly in relation to the effect of different stocks and pruning technique on the keeping quality of apples, has also been a feature of the season.

Other investigations have been concerned with storage disorders and with fruit physiology in relation to keeping quality and seasonal climate. Work on pre-storage treatments to increase the cool- and common-storage capacity has now been greatly expanded. A survey is also in progress in coastal Queensland areas to locate indigenous or naturalized plants, which may be sources of certain drugs such as caffeine, ephedrine, cocaine, quinine substitutes and substances such as derris. Attention has also been given to potato virus diseases, particularly to virus X, and trials have been made on fungicidal dusts for the treatment of maize seed. The dusts had no perceptible effect on germination or vigour of early growth, except at Canberra, and then only when inferior or diseased seed was used.

Laboratory work of the Division of Economic Entomology on weevil control has been concentrated chiefly on a study of mineral dusts, and gratifying results have been obtained with one or two effective non-silicious dusts readily available in Australia. Milling tests with treated wheat indicated that the dust is removed in the ordinary mill treating process, although the dust treatment has certain disadvantages such as its effect on the appearance and free running properties of the grain. Although the Division does not possess the special equipment required for accurate assessment of the relative toxicity of fumigants, a series of experiments with simple apparatus has been carried out to determine the susceptibility to fumigants of Calandra and *Rhizopertha dominica* to such fumigants as di-β-chloroethyl ether, chloropicrin, ethyl formate, *o*-dichlorobenzene, carbon disulphide, ethylene dichloride and carbon tetrachloride. Results indicate that Rhizopertha is more susceptible to all these fumigants than either of the Calandra species. Practical fumigation tests of infested wheat in concrete silos have been carried out with ethyl bromide and with Cyanogas G, the latter appearing to give almost complete control of *Rhizopertha dominica*. The sterilization of stack sites and sheds with petroleum oil and tar oil emulsions indicates that only those emulsions containing *o*-dichlorobenzene and di-β-chloroethyl ether or their mixtures with creosote and oil have given consistently good results for killing the developmental stages of *C. granaria*, *C. oryzæ* and *R. dominica*, and good results have been obtained with emulsions of carbon disulphide or *o*-dichlorobenzene with crude naphthalene in the treatment of wheat shed floors when these are of loose earth in which infested grain may be buried.

In investigations on sheep blowfly, considerable progress has been made in compounding two useful dressings, the study of repellents and in an investigation of the breeding-ground of *Lucilia cuprina*, which is responsible for 90 per cent or more of strikes in Canberra. Toxicity studies using the contact toxicity technique indicate that 0·4 per cent of arsenious oxide is completely non-toxic to prepupæ when immersed for 30 minutes at 23° C., and αα-dipyrridyl is almost as high in toxicity as nicotine, dinitro-*o*-cyclohexyl-phenol and proflavine being only slightly toxic. Other entomological investigations have been concerned with the eradication of cattle ticks, insecticides for the control of wheat weevil and on the oriental peach moth. Animal health and nutrition investigations have covered pleuro-pneumonia of cattle, mastitis in dairy cattle, studies on phenothiazine as an anthelmintic, and blowfly problems and coast disease of sheep.

The Division of Forest Products Investigation has extended its work in the field of defence including the examination of numerous specifications for all kinds of defence and munition needs, the submission of advice on substitutes when necessary, and recommendations in regard to modified manufacturing methods or procedures; its work is claimed to have resulted in savings in imports, in the amount of timber used and in the use of timber of lower quality. Flax investigations have been enlarged and both chemical and engineering research in this field are now centred in the Division. The promising work on chemical retting is being revived and problems of scutching, tow treatment, drying of retted straw and control of dew retting are also being studied.

Food preservation investigations have covered problems in the preparation and transport of boneless frozen meat, chiefly for the use of fighting services overseas, canning problems, the use of *o*-phenyl-phenol in fillers to restrict bacterial waste in stored eggs, the storage of whole egg powder, the handling, treatment and storage of fruit, etc., investigations which will in future be co-ordinated by a special committee representing all bodies carrying out work in this field. Protective skin coatings for fruit have been investigated, particularly the preparation of colloidal wax emulsions that leave clear bright films on drying. Chemical treatments for the control of mould wastage in stored grains have also been investigated. Fisheries investigations have covered smoking of fish, fish liver oil production, and investigations on Australian tunas, pilchards, mullets, etc.

Brief reference is made to the work of the National Standards Laboratory, to aeronautical investigations at the Aeronautical Laboratory, which has now been given the status of a Division, and to investigations in industrial chemistry, including that on unshrinkable wool, on wool wax, utilization of minerals and on producer gas investigations, particularly the suitability of Australian hardwoods for the production of charcoal. Substantial progress has been made in building up a research organization and the development of research methods for dealing with lubrication, bearing and wear problems in Australia. The work is undertaken as co-operative research with the University of Melbourne and housed in the new chemistry school. The work of the Dairy Research Section has included a survey of the properties of Australian butter and the storage and transport of butter fat without refrigeration.

NORTH SYRIAN ARCHÆOLOGY AND OLD TESTAMENT SOURCES

THE July-August number of *Man* contains, among other interesting matter, a résumé of the most recent results obtained by Commander Schaeffer at his Ras Shamra dig. North Syria was a very important area geographically in prehistoric times, and the excavations at Ras Shamra, like those of Mersin in Cilicia, alas scarcely more than begun, may well prove to be some of the most interesting in the Near East.

The early story of Ras Shamra goes back into Neolithic times, and a peculiar dark, incised pottery has been found in the lowest level, which, at Mersin, occurs in a definitely Neolithic milieu associated with a splendid industry made in obsidian. But at a later date Ras Shamra was a Bronze Age Canaanite town of considerable importance and the capital of the kingdom of Ugarit, well known in Egypt, Babylonia and the Hittite empire. It was a meeting-place of Minoan, Mycenean, Babylonian and Anatolian cultures. Cuneiform texts have been unearthed which reveal the Canaanite mythology and were at any rate one of the sources drawn upon by the writers of the Old Testament.

The last (1938–39) of the ten seasons of pre-war work has considerably strengthened our knowledge in this respect, having enabled certain documents to be accurately dated; and it would now seem that many of the Patriarchal stories of the Old Testament were not mere oral tradition collected by authors of the time of Solomon and later, but were part of a written heritage derived from the Canaanite Bronze Age. Furthermore, it would appear that some of the religious and moral progress achieved farther south by the great Old Testament prophets had already started some centuries earlier in the mother-civilization of that Israelite culture which has meant so much to the world.

The latest work also unearthed the royal palace-fortress, which was protected by square towers of massive stone-work and in which were found the royal archives. The contents of the palace as a whole were very interesting and included a fine gold encrusted battle-axe with an iron blade belonging to the end of the fifteenth century B.C., as well as the muster roll of the army of Ugarit, naming the officers and men and the number of bows and slings handed over to them. The tale of dismantling, restoration and final destruction which the excavations unfold seems to show that this kingdom of Ugarit with its capital of Ras Shamra finally went under at the beginning of the twelfth century B.C. to those same northern sea-borne invaders who effected the ruin of Troy. All this new information we owe to Ras Shamra and the labours of Commander Schaeffer and his archæological and literary helpers.

M. C. Burkitt.

FEEDING AND BREEDING OF *CALANUS FINMARCHICUS*

THE importance of *Calanus finmarchicus* in the economics of the sea is so great that more attention has been paid to it than to any other copepod. That Dr. F. Gross and Mr. J. E. G. Raymont are now able to keep the adults for months under controlled conditions is a very definite advance on former work, and the two papers now before us are full of interest and suggestive observations[1].

Dr. Gross[2], in previous experiments, had made successful persistent cultures of many diatoms, using "Erdschreiber" as medium (a combination of nitrates, phosphates and soil extract) and had specialized in extending the method to minute flagellates. The present work on Calanus depends on its feeding on these cultures—both diatoms and flagellates—and its main importance lies in the fact that such food is found to be sufficient for the adults during their normal life-time. It is shown conclusively that for long periods Calanus can live entirely on a diatom diet, or one of diatoms and flagellates together, provided that there is a large amount of the food present, much more than under natural conditions in the sea. For a shorter period, they can live on flagellates alone. Nicholls[3], from field data, placed the life of an adult female at about six weeks. In Raymont's and Gross's large cultures of females, more than half the animals generally remained healthy for three to nine weeks, while a few were kept active for more than a hundred days. The maximum number of adult animals which could live successfully in 200 c.c. Erdschreiber medium, with excess of food and weekly change of medium, was approximately twenty. Adult males did not live so long as the females, and this is probably what takes place in Nature, as has already been suggested by Ruud[4]. The present experiments show that the females feed more actively than the males, the number of fæcal pellets being more than 2–10 times as great and the size of the pellets of the females greatly exceeding those of the males. The moulting of Stage V was found to be a critical stage when many specimens died.

The diatoms used included large and small species, the large Ditylium being specially useful. That *Calanus finmarchicus* is a mixed feeder in its natural surroundings is well known, and it has been shown by Lebour[5] and Marshall[6] that Crustacea remains are sometimes to be found in the gut contents. Marshall states that "a certain proportion of Calanus are always found eating crustaceans". She found that 7–48 per cent of the guts examined contained Crustacea, according to the season, and they were usually taken where there were few diatoms about. It is therefore important to know that Crustacea can be dispensed with. Lowndes[7] clearly shows that the varied movements of Calanus indicate different methods of feeding at different times and from the anatomy of the mouth parts that it should be able to catch and select food. Harvey[8] has made observations in this connexion from which it is probable that, while the small diatoms are filtered, the larger species are caught by the mouth parts. It appears that Calanus is able in this way to select its food and does not depend entirely on its filtering mechanism.

Crawshay (see Lebour[9]) reared Calanus in the Plymouth Laboratory through the whole of its life-history, feeding it on Nitzschia. Raymont and Gross reared it as far as the fourth naupliar stage only. It should be very easy, however, to continue the experiments on the present lines, and rear it through all its stages. They found that a constant temperature, 5°–12° C., is essential for all these experiments, but spawning was apparently less prolific; hatching and subsequent growth of the nauplii was poorer and moulting of the Stage V copepodite was less successful at the lower temperature.

The eggs swelled up enormously when released from the oviduct into the water, and they always fell to the bottom of the vessel. The second paper deals with the specific gravity of the eggs, nauplii, Stage V and adults, estimated from the rate of sinking of anæsthetized specimens in sea-water and solutions of different density of gum arabic in sea-water. The eggs are not buoyant but sink in sea-water at a rate of about 2·5 cm. per minute. The density of the eggs is almost the same as that of the nauplius and adults (male and female), but there is a surprising difference in Stage V, the specific gravity of which is only slightly higher than that of the sea-water used, namely, 1·0255–1·0265 (eggs 1·045–1·049, newly hatched nauplii and males and females 1·043–1·047). The authors suggest that the low density of Stage V and the consequent economic use of its fat reserves make this stage suited best for tiding the species over the winter months.

FORTHCOMING EVENTS

Wednesday, September 16

INSTITUTE OF MARINE ENGINEERS (at the Institution of Mechanical Engineers, Storey's Gate, Westminster, London, S.W.1), at 5.30 p.m.—Dr. S. F. Dorey: "Reduction Gearing for Marine Steam Turbines" (Parsons Memorial Lecture).

Friday, September 18

PHYSICAL SOCIETY (OPTICAL GROUP) (in the Physics Department of the Imperial College, Imperial Institute Road, London, S.W.7), at 3 p.m.—Dr. C. R. Burch: (1) "Some Applications of the Optical See-saw Diagram"; (2) "The Evolution of a Reflecting Microscope Objective". Mr. J. L. Houghton: "Combinations of Spherical Lenses to replace Non-spherical Refracting Surfaces".

Saturday, September 19

INSTITUTE OF PHYSICS (JOINT MEETING OF THE MANCHESTER AND DISTRICT BRANCH AND THE INDUSTRIAL RADIOLOGY GROUP) (in the Physics Department of the University, Oxford Road, Manchester), at 2.30 p.m.—Dr. R. Jackson: "The Radiography of Heavy Metals".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEAD OF THE DEPARTMENT OF PHARMACY AND BIOLOGY—The Principal, Central Technical College, Suffolk Street, Birmingham 1 (September 19).

LECTURER IN MECHANICAL ENGINEERING—The Clerk to the Governors, Mining and Technical School, Heanor, Derbyshire (September 21).

MALE TEACHER (GRADUATE) OF ENGINEERING MATHEMATICS AND SCIENCE at the Oxford Schools of Technology, Art and Commerce—The Chief Education Officer, City Education Office, 77 George Street, Oxford (September 21).

ASSISTANT IN AGRICULTURAL ECONOMICS SECTION OF THE DEPARTMENT OF AGRICULTURE, FOR FARM COSTS INVESTIGATION—The Registrar, The University, Leeds (September 21).

DIRECTOR OF THE CHEMICAL RESEARCH LABORATORY, TEDDINGTON—The Secretary, Central Register (Ref. F690), Ministry of Labour and National Service, Sardinia Street, Kingsway, London, W.C.2 (September 30).

LECTURER IN MECHANICAL ENGINEERING—The Director of Education, The Polytechnic, Regent Street, London, W.1.

CHIEF ENGINEER—The Secretary, Derby Gas Light and Coke Co., Gas Offices, Friar Gate, Derby.

BIOCHEMIST to work in the Department of Pathology under the direction of the Pathologist—The Pathologist, Royal Infirmary, Preston, Lancs.

PUBLIC UTILITIES IN RECONSTRUCTION

THE eleventh report of the Select Committee on National Expenditure gives fresh pertinence to the discussion in the House of Lords on the extent, control and management of the essential public services, which Lord Reith initiated, and Mr. Bevin's speech to the National Chamber of Trade on July 15 also raised these important questions as to the exact relations between Government and industry and the nature and extent of State intervention. Whatever concern may be felt as to the capacity of the Civil Service in this respect, no report that has fairly faced the issues involved in reconstruction fails to recognize that some large measure of intervention will be necessary for a prolonged period after the War. That follows at once from the recognition that the Government must assume responsibility for creating the social and economic conditions in which our objectives of economic security, steady employment, greater equality of opportunity and distribution and a rising standard of living can be secured.

From the point of view of the relations between the State and industry, Government has two functions. The first, which is negative, is to act as referee between the various economic groups, to secure and maintain economic freedom and remove the present institutional defects—the tendency towards combinations in restraint of trade, the resistance to adaptation to new circumstances which nearly always develops from monopolistic practices, and the power of managers of industry to make decisions which may vitally and even adversely affect the interests of the community without being accountable to the community. This function probably involves revision of the patent laws. It certainly involves constant vigilance and control over monopolistic practices, a new code of industrial behaviour, some modification of the Companies Act, and more publicity from companies about their activities.

The second function of Government is positive and directive. It is that of ensuring that the whole community is properly fed, clothed and housed, and preventing the periodic recurrence of large-scale and demoralizing unemployment. In certain spheres it may involve the subordination of the profit motive to social incentive, though there should remain a vast area of industry and trade in which the fullest possible scope is given to enterprise and profit as the mainsprings of efficiency, adaptability and enterprise. The main problem is that of harmonizing the interests of the economic groups and those of the community, of reconciling freedom and security without losing the driving force of enterprise.

It is when we enter on the discussion of the evolution of the suitable technique of control that the main difficulties arise. No single formula is suitable for all purposes and for all forms of economic activity which it is desirable to control or supervise. Some activities or industries might be taken over entirely by Government. In this category fall certain public services and industries that have reached an advanced stage of development. For this the Post Office or the public corporation might serve as the model, and it was to this aspect that Lord Reith directed special attention in his speech in the House of Lords on June 17. Stressing the importance of giving the ideal of public service precedence over other factors such as political considerations and the profit motive, he emphasized the importance of efficient and disinterested administration and appeared to advocate a considerable extension of the public utility corporation. He suggested a National Transport Corporation covering railways, road transport, canals, coastwise shipping and internal air services, and urged that the railways should be brought under unified management and become part of the Corporation. In some measure central regulation and control are required in the building and civil engineering and building materials industries, both to settle prices and to secure economy in materials and machines, standardization, and the adoption of codes of practice and research.

Lord Reith would amalgamate the Central Electricity Board and the Electricity Commissioners, with the object of securing a uniform price for electricity over the whole of Great Britain. Gas and water, roads and river management, sewage and subsoil water are other services in which there are too many authorities and too many types of authority. While the duties and responsibilities of the public corporation system would be defined by the State in charter and statute, and Parliament would be consulted on policy, Lord Reith would give them the same freedom in organization and management as in commercial undertakings.

The nature and extent of the public services to pass under Government control may be the subject of debate. Lord Strabolgi was somewhat critical of Lord Reith's suggestions. He agreed that it is essential that our plans should be made known and accepted, and that we should plan for peace as we should have planned for war. So far as transport is concerned, his emphasis was laid on overseas transport, and civil aviation must also be included. He believes that all external transport should come under some measure of State control. Viscount Bledisloe also agreed that there must be very considerable control of transport and even in agricultural production for many years after the War; that, he said, need not imply or justify State ownership, and he stressed the importance of getting away from the party point of view and of being prepared to make sacrifices in our political outlook in order to obtain something like national unity and co-operative effort.

In spite of these differences of opinion as to the services to be controlled, there is widespread agreement as to the importance of leadership and of finding the men to carry the great responsibilities involved. Lord Strabolgi believes that the new aristocracy of leaders required will emerge from the War in young men and women who can be trusted to put public interest before the profit motive, and to manage these great undertakings efficiently. Lord Reith, however, thinks that our lack of institutions has prevented us from getting full value from the key men. Individualism is still required. Key men must be trusted, and governors and managers permitted to exercise their natural functions of governing and managing the corporations they serve, and to which and for which they are responsible. A planned society should be a free society, and it should and must be planned for freedom.

It is because the tradition of the Civil Service, with its caution, love of precedence and the Treasury methods of control with their emphasis on higher authority rather than on efficiency, does not encourage initiative or even a proper sense of responsibility in departments, that whatever form or technique is used for extending the measure of Government control, the day-to-day operation of the services and industries concerned should be entrusted to competent managers rather than to Civil servants. Lord Reith indeed suggested that Civil servants should not be concerned with the management of essential public services, and that the postal services, including telegraphs, telephones and wireless services, though now highly efficient, would be notably more so if they were not a Government department subject to Government methods of financial accounting and control, and that the same remark might apply to such other services as pensions and insurance.

The realization of this inherent weakness in the Civil servant lies behind the discussion which recently took place regarding the headship of the Civil Service, and reflects the criticism of Treasury methods of control and outlook contained in the Haldane report on the Machinery of Government, and discussed last year in a PEP broadsheet.

An illustration of the incapacity of a Government department in management matters is provided by the report of the Select Committee already mentioned. This inquiry into the working of the royal ordnance factories reveals clear signs of failure to plan with sufficient attention to securing a proper balance between the various parts. For example, in regard to filling capacity and the capacity for the manufacture of components, although at one factory 57 per cent of the floor space is at present lying idle, no record of the total amount of unused capacity is kept at the headquarters of the Ministry of Supply, and the Department was unable to make more than a rough guess at the total amount in all factories. Indeed, it was not considered the Department's business to know. Similarly, the redundancy of labour in factories affords evidence of failure to exercise sufficient forethought and to adapt actual arrangements to probable future developments. The discrepancies in the estimates of redundancy which exist between the headquarters officials and those actually in charge of factories indicate another aspect of faulty organization. The division of responsibility for royal ordnance factories, and the confused dispersal of responsibility for matters affecting the handling of labour tell the same tale of failure to recognize the importance of a clear appreciation of the proper functions of the various parts of the organization.

What is particularly disturbing is that the importance of matters of organization was specially stressed in the Select Committee's Seventh and Eighth Reports, which emphasized the necessity of replacing hasty improvisation by carefully balanced plans which ensure the best possible use of the limited resources of Great Britain. The need for the clear planning of programmes based on an accurate appreciation of existing factors and probable future developments was specially stressed. These warnings, like many of the habitual tools and techniques of modern industrial management, have been sadly disregarded in general and in detail.

On the organization side, neither at headquarters nor at the factory has the machinery been provided to integrate the responsibility for the various specialist functions and services. In the factories, effective control by the superintendent has been hampered by the encroachment of specialist authorities, a tendency encouraged also by the regional administration of filling factories. Functional control has been carried too far, and the recommendation for placing the control of all types of royal ordnance factories under one director-general is accompanied by the further recommendation for the transfer to him of all labour questions inherent in the management of the factories or administered by separate authorities. The deputy-director-general responsible for labour should not merely have full access to all relevant information, but should also be brought into consultation at every stage in all matters involving major questions of policy. He should not be concerned with those matters of labour supply, such as recruiting, which are the proper concern of the Ministry of Labour.

Of the twenty-four recommendations of this report, there is not one which would not be endorsed or adopted by industrial management as a matter of course, and some of them indicate a startling contrast between the practice and outlook of the Ministry and that of industry. The accumulation of stocks of materials and components to secure a proper flow of supplies; attention by the designing staffs to ease and economy in producing the completed product, and full testing from the production point of view of every design before acceptance; the application of statistical methods of control of manufacture to all suitable items of production; time and motion studies and the introduction of incentive bonus schemes; uniformity of methods and standards of inspection for the various products and factories; and the regular exchange of visits and of records and other documentary information between the superintendents of royal ordnance factories and the managers of private firms engaged on similar work—these, to take only a few points, are so much the accustomed practice in industry that it is astonishing that a Select Committee should find it necessary to make recommendations on such specific practices.

The significance of these details lies in the revelation they give of the extent to which the Civil Service has fallen behind industry in its use and knowledge of organization and scientific management. Insufficient liaison between design and production departments, for example, like the strictures in the report passed on the errors in siting and designing hostels due to insufficient regard for local information and for the desires of the workers, or like the failure to deal seriously with the problems of absenteeism, or the replacement of men by women, is primarily a reflection on management, and as such demands prompt action by the Minister of Production. The country is fast becoming impatient of a state of affairs in which continued neglect of informed, responsible and constructive criticism of the type which characterizes these reports of the Select Committee is possible.

This report undoubtedly adds great weight to that important volume of opinion voiced by Lord Reith, as well as, for example, by Mr. Samuel Courtauld in his article in the *Economic Journal* (Reprint, Macmillan and Co., Ltd. "Government and Industry: Their Future Relations", 1942, 6*d*. net), which is against direct Government control of industry, though the necessity for control is admitted. Whatever method of control is adopted—and there are other methods to be explored as well as that of the public corporation—it is essential that there shall be full control over the controllers on behalf of the community and to ensure efficiency. It may be sufficient in some particular services or industries to exercise control over general policy, with free play for private enterprise and the profit motive. Again, some essential services might be deliberately subsidized to make necessities available at a low price; or again, we might explore the possibility of nationalizing the costly equipment of certain industries, leaving their management in the hands of private enterprise.

Whatever method be adopted, there is no reason why Parliamentary control or criticism should be excluded, particularly on questions of policy, and any attempt to screen the public corporation from such control would be unwise. Equally, it is certain that the separation of day-to-day control of public services or industry from the Civil Service should not render the reform of the Civil Service less imperative or afford any pretext for shelving the attempt to bring a new outlook, greater flexibility and modern technique into the Service, while retaining the great traditions and great qualities which have justly won it the respect and admiration of the world.

On this point Mr. G. D. H. Cole has an interesting contribution in a recent issue of *Public Administration* (20, 1; 1942). Writing on reconstruction in the civil and municipal services, he considers that neither the national nor the local public services are likely to revert to their pre-war methods and traditions. The war-time changes have left too deep a mark, and large changes are desirable in view of the changing functions of national and local government and of the need for extensive readjustments in the very structure of the machinery of government.

Mr. Cole limits himself mainly to the personnel side, and urges that we must consider afresh the qualities we chiefly require in the public services of the future, and the methods of training, recruitment, promotion and movement within them which are most likely to bring these qualities to the fore. This involves, of course, some consideration of the relation between the public services and other types of professional employment, and particularly the relation between conditions in the semi-public services or public utility concerns and those in the public services or in private business. The twelfth report of the Select Committee on National Expenditure, although dealing particularly with two appointments in the Ministry of Works and Buildings, certainly raises doubts as to the soundness of the present practice. The conditions laid down by the Treasury to facilitate the appointment of able men who are expert in a special sphere are obviously open to abuse, and the dangers in wide disparity in the remuneration of the same type of work and ability by the State and in private industry should need no further emphasis.

The reform of the public services in this way is not exclusively a matter for those who control these services; it also concerns those whose task it is to shape the educational system in conformity with changing social needs. Thus Mr. Cole concludes that, next to plain honesty, the quality which the Civil Service will be called upon most to display in the work of reconstruction is adaptability. This is just the quality in which it is most lacking to-day. To remedy it, Mr. Cole suggests a greater diversity of experience, greater direct acquaintance with the things and persons affected for good or ill by the decisions of Civil servants, and a wider basis both for recruitment at varying ages and for promotion to the key positions of authority. He looks forward to a drastic overhauling of the municipal services, leading to much higher standards of recruitment and possibly to frequent interchange between the service of the local authority and the service of the State, thus enabling Civil servants in the departments affected to have periods of service away from the centre. A further advantage would be the gradual disappearance of the unfortunate sharp demarcation between the national and municipal Civil services.

Besides welcoming some disturbance of the excessive security and tranquility of the Civil Service, Mr. Cole maintains that the administrative qualities required for the highest offices are not to be found only among the higher non-technical administrators from whose ranks they are usually filled; he anticipates a large new infusion into both services of technical and professional elements, and the breaking down of the lines of demarcation between these elements and the ordinary administrative grades. This should be a natural result of the demand for the services of widely diverse types of specialists in reconstruction, as well as for the permanent expansion of the social services.

Measures such as these, which have been frequently advocated during the last decade, should do something to bring a more democratic, imaginative and adventurous spirit into the Civil Service than in the past. They inevitably involve some disturbance of the severely cloistered life which many Civil servants are accustomed to enjoy, and if at the same time there is exercised the power of compulsory retirement where a Civil servant has shown himself unfit for his post, a matter on which Mr. Cole, like the P E P broadsheet, lays great emphasis, there should be less difficulty in instilling and maintaining initiative and efficiency in a service which has deservedly earned for itself a world-wide reputation.

PHYSICS IN BIOLOGY

On Growth and Form

By Sir D'Arcy Wentworth Thompson. Revised and enlarged edition. Pp. viii+1116. (Cambridge: At the University Press, 1942.) 50*s*. net.

IT may seem sufficiently obvious that living tissue is to a large extent subject to physical and chemical laws; if a man falls off a cliff he is as much subject to gravity as a stone is, and the action of nitric acid or excessive heat on skin is much the same whether the skin is alive or dead. Sir D'Arcy Thompson's well-known work, now in its second edition, gives many illustrations that are less obvious. The author finds that at all stages of growth the mode and rate of formation of new tissue are largely determined by the form of the organism at the time; and since this in turn determines the rate and distribution of growth, the development is reducible to differential equations with regard to the time.

It would be impossible to give a summary of a book that is itself a summary, indicating prodigious learning. A few examples may, however, be given. There is a very promising attempt to reduce nuclear division to physical processes: the explanation of the forms of the septæ of Nautilus and of cell-walls in terms of surface tension looks complete. The formation of buds is attributed to a local concentration of potassium salts, which reduce the surface tension locally, and the surface is pushed out farther by internal pressure. The increased curvature increases the local adsorption of potassium, and we have an instability leading to a bud. But what determines the spacing of buds on the stem? Apparently, for less than a certain interval, the budless stem is stable, and it is not easy to see why. Such difficulties should lead to further investigation, and the attention of mathematical physicists might be directed to them. Fortunately, the author's language is not of the type common in biological writing, where about one noun in three may convey any meaning to a non-specialist. He does, however, sometimes use a physical term in a non-physical sense. For example, in discussing nuclear division he speaks of the importance of inertia (p. 309). On this scale inertia, as a physicist understands it, must be negligible in comparison with viscosity; and I cannot see what other meaning is intended. "Vector" is used in an unusual physical sense on p. 78.

It is a pity that in the discussion of energy relations in propulsion no reference is made to the fact that the square law of resistance only holds above a certain velocity depending on the size; below this velocity a linear law holds, and may be the right one for small organisms. It is not true, as stated on p. 31, that in an unstreamlined body the drag increases as the cube of the velocity; it is nearly as the square, but with a larger coefficient than for a streamlined body. On p. 43 it is stated that birds and aeroplanes are helped to fly by the compressibility of the air; this is not so, compressibility being practically irrelevant so long as the velocity is less than that of sound. With regard to the normal law of errors (p. 124), a correct statement would be that deviations equal to the standard error divide the area of the curve nearly in the ratios 1 : 4 : 1 and coincide exactly with the inflexions. In the allusion to the advantage of a long narrow wing in birds, explicit reference to the reduction of induced drag would be beneficial. An experiment is mentioned on p. 565 as providing a strong argument that general shrinkage does not account for the pattern of the earth's crust. This is surprising, because the irrelevance of the experiment was pointed out at once in the same journal; it was a case of elastic instability, which is easily produced on a laboratory or workshop scale. but not in the earth's crust as a whole. A rhumb-line on a sphere is not a great circle (p. 675).

It appears that the opinions propounded in the book have been regarded as antagonistic to natural selection and that the author acquiesces in that opinion. I do not see why. Surely it is possible that the more an organism can leave the physical and chemical processes to look after themselves, the better adapted it is to its environment. A machine is considered better the less frequently it needs special attention, and the same may be true of an organism. Mother Carey's "I can make things make themselves" may be the remark of a profound biologist. Also, if life is most efficient when most of its processes can be left to physics and chemistry, the difficulty of finding direct evidence for a specific 'life force' is explained on a vitalist theory and ceases to be an argument against it.

I think that most of this controversy arises from a failure to state the question properly. I quote from pp. 14–15. "Where physical science reaches its limitations physical science itself must help us to discover. Meanwhile, the appropriate and legitimate postulate of the physicist, in approaching the physical problems of the living body, is that with these physical phenomena no alien influence interferes. But the postulate, though it is certainly legitimate, and though it is the proper and necessary prelude to scientific inquiry, may some day be proven to be untrue; and its disproof will not be to the physicist's confusion, but will come as his reward." But what is discussed in this passage is not a postulate at all, but a considered proposition. If we assert that no alien influence interferes, we assert that this statement will never be proved untrue, and there is no occasion to discuss what will happen if it is. If we assert that some other influence does interfere, and make use of the statement that none does, we contradict ourselves at every turn. It is precisely because we neither assert nor deny the proposition that there is any need to investigate. But a postulate must be an asserted proposition. A considered proposition, however, is simply one possible answer to a question, in this case that physics can account for all the phenomena. The scientific urge comes from considered propositions and is hindered, if not destroyed, if they are prematurely asserted. The paradoxical conclusion of the above quotation is, in fact, the result of a verbal confusion, which is none the less dangerous for being a common one.

Further, I have followed the distinguished author in assuming that we do know what we mean by "living". But do we? We may agree that a flying swallow is living and that a stone is not; but have we any empirical criterion that we can apply in every instance? Without one the proposition enunciated is not even intelligible.

Again, Sir D'Arcy says (p. 650) that it does not help us to say that molecular asymmetry may have originated in fortuity. But there is a close enough resemblance between the earth and Venus for us to suppose that life could have developed on Venus; and recent work makes us confident that it has not done so. I think that it does help us to say that an extremely rare event happened once on the earth and never happened on Venus. In any event, though anybody making a living organism in the laboratory would probably get a Nobel Prize, we are warned against suggesting it as a problem to a Ph.D. student.

It is superfluous to recommend the book to biologists, who will know enough about the first edition; to them the reviewer need only say that abundant attention has been given to later work. But mathematical and experimental physicists will find in it, at the least, extremely interesting reading, and some of them, one may hope, suggestions that will repay further research.

HAROLD JEFFREYS.

MEASUREMENT OF TREES

Measurement of Trees
By Reginald Davey. Pp. 236. (Nutley, Sussex: The Forest Press, 1942.) 21*s*.

IN his book, Mr. R. Davey tells us that the work is the outcome of three years research into British commercial methods. "It is", he says, "the first systematic study of the ocular system of measuring growing trees." His laudable object was a simplification of methods of measuring trees and woods for sale, "so that the exercise of care can secure results at present attainable only after years of practice". One of the chief objects of the research work was the much-vexed question of 'taper' in the bole.

Officers of the Forestry Commission have undertaken a considerable amount of investigation into this matter in the case of conifers. With regard to hardwoods, there should be no quarrel with the author's work, statistical tables, and views, if it is understood clearly that they are drawn up for present conditions and existing woods in Great Britain, where true forest management and sylviculture, with few exceptions, have been admittedly absent. Consequently, as a general rule, the boles of the trees in a wood develop a taper which it is the object of good sylvicultural treatment to reduce to a minimum. Nature, in the natural forests of the world, as a result of considerable profusion and waste and long periods of time, produces the final product in a bole resembling more and more the cylinder, between the base of the stem and the point at which the main branches take off. This is a common sight in the tropical forest. The same is observable in the coniferous belt in northern Europe. Moreover, in the case of some of the well-managed oak and beech forests in France, worked on rotations of 180–200 years, the bole, that is, the merchantable timber part of the tree in which the author is interested, is far nearer the cylinder than the cone or paraboloid, and does not resemble the diagrams in his Fig. 1. Moreover, the buttress or 'root-swelling' in the case of these latter is restricted and has little resemblance to the author's neiloid—so much so that the French practice is to dig a small trench and expose the basal parts of the root system and fell the tree by severing the roots near their junction with the stem.

In a book based on research work which should have a considerable value in Great Britain it appears that the above points should be placed in their proper perspective, a perspective which emphasizes perhaps the value for Britain of the work, in view of remarks such as the following. Mr. Davey writes: "Trees rarely resemble either cone, paraboloid or neiloid for their whole length." If by 'whole length' the author implies timber length to the main branching, even in the case of conifers it is evident that he has never seen a great deodar (*Cedrus deodara*) standing in the forests of the north-west Himalaya. Again we read: "Owing to heavy branching there is less uniformity in the stems of hardwoods . . . the branches are seen to be larger in proportion to the stem, set on the stem less evenly and generally to affect the shape of the stem for a greater part of the length." While this description probably applies to 90 per cent or more of the hardwoods grown in Great Britain, it would not be accepted by anyone who has seen an old teak, s'al, deodar or mahogany tree in a fine piece of virgin forest, or oak in well-managed long rotation forests in France. The book is well illustrated with plates and text-figures, and its get-up, in these days, is a credit to publisher and printer. E. P. S.

SOCIAL GEOGRAPHY IN INDIA

Man and his Habitation

A Study in Social Ecology. By Prof. Radhakamal Mukerjee. (Lucknow University Studies, No. 12.) Pp. xv+313. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1940.) 8*s*. 6*d*. net.

THE relations of man and society are a prominent subject of contemporary discussion. Traditional links everywhere are weakening and new experiments are to the fore. In many books we read discussions that, often unconsciously, presuppose a European or North American background; but, in this case, the background is Indian and the differences in facts adduced as well as in lines of argument make a reader wonder whether there is really such a subject as social science or whether there are not rather numerous 'social geographies' to be studied.

The author thinks that it is useful to study society, in its relation with habitation, under three heads, namely, density (of population, of dwellings, of groups, and so on); mobility (including mobility of status as well as mobility of persons and of groups and their habitations); and distance (including here contrasts of status as well as distance in the physical sense). Density, mobility and distances are thus to be studied with special reference to their social and institutional implications. All through his book the author is specially concerned with the contrasted implications of urban and rural life, particularly in India, but also in the United States and, to some extent, in Europe.

Relatively high density, quick mobility and sharp social division or distance are considered to be features of urbanization under which human relations tend to become transitory, segmental and superficial, regulated by more or less rationalized contractual arrangements; whereas a lower density, a much slower change and a closely graded hierarchy taking more account of personal skill and worth are, for him, features of rural life. He nevertheless sees that there is an up and down movement of caste groups, yet not a sufficiently rapid change to upset the solidarity of the village. The thought behind this is essentially that expressed by Sir Henry Maine in his view of the gradation from status to contract and from kinship to neighbourhood. While Mukerjee expatiates on the evils of urbanism, he sees also the weak side of Indian village life—the tenacious conservatism, the unthriftiness in land-use, fright and ill-treatment in the hands of money-lender and landlord, and wide dominance of superstitions that the rationalizing processes of urban life may later on too easily transform into a subservience to mass emotion.

Sometimes the author seems to continue the old error of so many writers on social subjects in supposing that a nomadic pastoral stage of society intervened between the earlier one of hunting and collecting and the later one of food production by cultivation. All the indications we have, admittedly still insufficient, go to show that from hunting, mainly by the men, and collecting, mainly by women and children, society often graded to cultivation (by the women and later by the enslaved men of conquered or client groups). Herding may have arisen in different ways in different cases, but seems more often to have developed as an accessory to cultivation rather than as a preliminary to it. The communities that depend almost entirely on flocks and herds are usually highly specialized ones, though cases are known in which they have become transformed, usually under external pressure, into cultivators. If Mukerjee does tend to put pastoralism before cultivation sometimes, he, at any rate, sees it is associated with certain environments unfavourable to cultivation because of upland positions, drought, etc.

He has a good deal to say concerning the boys' dormitory, with sometimes another for the girls; and his section on the early evolution of habitation in India in its relation to forest clearing by fire for shifting cultivation gives an interesting sequence that emphasizes the great and widespread importance of the aboriginal, if to some extent Hinduized, elements in Indian life. The village dormitory for boys, the houses of the advance guard, housing of a slightly better type for the headman and his kinship group and in due course for the ceremonial leaders in process of evolution towards a priesthood, as well as the menstruation hut are all reviewed. A place in a grove may become the centre of ceremony, but the temple may also arise from a house under which burials have taken place and whence ancestral spirits may come into the women for rebirth. An unpartitioned communal hut may be an alternative, or even a still earlier, feature. There are people such as the Kabuis in Manipur who hold on to one and the same village site and yet shift their area of cultivation year by year in a set rotation. Houses come to be arranged around a dancing floor, and separate quarters of the village are differentiated for diverse kinship groups, with the unkempt hangers-on relegated to an outlying patch as untouchables. One may note for comparison the gipsy quarters appended to many east-central European villages and some of the "little Londons" hanging on to small English towns.

Mukerjee has much to say concerning the Panchayat, which, on the whole, he tends to idealize and wants to see revived in towns as well as villages. The Panchayat may be an assembly of elders of a village or a caste-group in a large village, and it has in the author's opinion checked the alliance of urban and rural capitalism which he seems to fear as an agreement between kites and crows at the expense of sparrows. In some of his reflections on Europe there is a tendency to ascribe to capitalism changes that have come largely through the use of root crops.

From different chapters one gets interesting hints as to diversities between different provinces and regions in India, and the whole book leaves one with a sense of the vitality of the Indian villages and a wish that the author had given us a book on India and had foregone rather less profitable general sociological surveys, though his knowledge of countries outside India compares more than favourably with the knowledge of some noted European writers concerning peoples outside Europe. Mukerjee's book is inspired by the hope of a planned economy in which durability of relationship will once more increase, and intimate touch with the land and personal loyalties shall have their chance.

H. J. FLEURE.

A PROBLEM IN ECONOMETRICS

The Analysis of Economic Time Series

By Harold T. Davis. (Cowles Commission for Research in Economics, Monograph No. 6.) Pp. xv+620. (Bloomington, Ind.: The Principia Press, Inc.; London: Williams and Norgate, Ltd., 1941.) 5 dollars.

ECONOMETRICS may be described as the application of mathematics to statistics for the elucidation of economic forces and the measurement of their effects. Since these actions are dynamic the principal data are successive records in time, or time series, and in recent years many mathematical economists have made them the subject of intensive study. Mr. Harold T. Davis has brought together and criticized the theories and methods employed in this region, and illustrated them with a wealth of new material. His summary of his subject is (p. 59): "The problem of single time series is concerned with three things: first, the determination of a trend; second, the discovery and interpretation of cyclical movements in the residuals; third, the determination of the magnitude of the erratic element in the data. This preliminary problem, once solved, leads immediately into the more complex one of discovering valid interactions of one time series with another. Upon the discovery of such relationships the hope of establishing a firm science of economics inevitably rests. From them will come ultimately the power of prediction, which is the final test of any mature science."

The Trend. If there are causes of a permanent or organic nature that affect the whole series, we may expect that their effects can be expressed by mathematical formulæ, or by some smoothing process. Thus a straight line, parabola or polynomial, applied to the terms or their successive ratios, may give a general picture of the movement over a long period, and leave residuals the algebraic averages of which over short periods are zero. Continual growth, as of population or production, may require an exponential expression, usually with a damping term; that most used is the 'logistic', the equation of which is $\frac{dy}{dt} = \frac{y}{a}\left(1 - \frac{y}{L}\right)$. In the author's opinion such curves can be successful only if they are based on some a priori theory. Failing any successful choice of an equation, the alternative is the device of the moving average, or some other arithmetical method of smoothing.

Cyclical movements. The mathematician naturally turns to harmonic analysis to determine the existence of, and to measure, regular periodic movements, and Mr. Davis devotes a great deal of his book to the nature and use of the periodogram and to the periods indicated by it in a number of selected series. The periods most generally found are seasonal, which require no logical explanation, and the 'trade cycle' for the genesis of which many ingenious theories are considered in Chapter 8. There is also a persistent 40-months cycle in stock exchange and allied series, for which no cause has been assigned. It is a weakness of harmonic analysis as applied to economic series, that it can reveal only waves of uniform length, whereas the length of the trade cycle has perhaps varied from seven to eleven years during the past hundred years; if the effect of a nine-year period is removed, new and irregular residuals are introduced.

Residuals. The effect of the removal of the trend and cyclical movements is measured by the reduction of the 'variance' of the series. Thus, if s is the original standard deviation, we may write

$$s^2 = s_t^2 + s_h^2 + s_v^2,$$

where s_t, s_h, s_v are the standard deviations attributable to the trend, the harmonics and the residuals respectively. The relative sizes of these squares are taken as measuring the 'energy' of the three factors. The residuals, though free from systematic movements, may nevertheless have some structure; as for example, an increase may be followed by a further increase more often than by a decrease, and autocorrelation (correlation between one term and a later term) may be present. The author devotes an interesting chapter to the study of random series, with reference also to the possibility of forecasting movements when there is autocorrelation. But perhaps the main importance of s_v is as a measurement of the magnitude of the variation that may be expected from unassignable causes. The behaviour of a series as regards trend, cycle and nature of the residual is clearly an important subject of observation; but study of the relationship between two or more series is more fundamental for econometrics. For this purpose the correlation of the residuals, x_t and y_{t+s}, from two series is computed for various values of s, the number of terms lagged (s zero is itself important). The usual process, followed by Mr. Davis, is to compute the correlation coefficient for several values of s, and select the maximum; thus we have the following coefficients between stock-market quotations (the Dow-Jones averages) and pig-iron production (s in months)

s	r	s	r	s	r
− 12	− 0·182	− 3	0·166	+ 6	0·568
− 9	− 0·130	0	0·515	+ 9	0·369
− 6	− 0·036	+ 3	0·684	+ 12	0·130

From this, Mr. Davis's conclusion (p. 105) is: "This means that pig-iron production follows by three months the industrial averages", and later (p. 235), this becomes, "It was established that pig-iron production moves three months after the stock price averages". Surely this is too strong a statement; the correlation coefficient is only an average, only one of several possible averages; a relationship is no doubt shown, but action based on it would by no means always be successful.

Space does not permit even allusion to all of the many topics discussed, or criticism of the less mathematical chapters on wealth and other economic subjects, which are less guarded than the purely analytical studies. Parts of the book are very difficult reading, and only possible to a qualified mathematician, who should be prepared to refer to the originals of studies where results are only summarized. The whole is a very valuable account of the work that has already been done in this important region, while at the same time many indications are given of promising lines of approach towards the basing of some parts of economic theory on a quantitative basis.

A. L. BOWLEY.

CATALYSED POLYMERIZATION OF METHYL METHACRYLATE IN THE LIQUID PHASE

By PROF. R. G. W. NORRISH, F.R.S.,
and R. R. SMITH
Department of Physical Chemistry, Cambridge

USING benzoyl peroxide as catalyst, Norrish and Brookman[1] found that the order of the polymerization reaction of undiluted methyl methacrylate is approximately zero in the first stages; the initial rate of reaction is proportional to the square root of the catalyst concentration[2]. The rate of reaction was found to rise markedly after about 10–20 per cent polymerization, and at the same time considerable heating of the system took place. Norrish and Brookman supposed that the temperature rise caused the rate increase, the former arising from a decrease of thermal convection in the system with increasing viscosity during polymerization. After experiments on catalysed and uncatalysed reactions, Schulz and Blaschke[3] took the opposite view, namely, that the rate increase mainly caused the temperature rise, and supposed that the former was due to an increase in the rate of initiation of active centres.

In order to test these two views, we polymerized methyl methacrylate slowly in narrow glass tubes (4–5 mm. internal diameter) at 60°, 40° and 25° C., using less than about 1 mol. per cent of benzoyl peroxide. The extent of reaction was measured dilatometrically up to about 40–50 per cent change. Under these conditions, we found that the rate of polymerization was nearly steady in the initial stages (up to 12–26 per cent polymerization, depending on the temperature and catalyst concentration), yet afterwards quickened to about 5–10 times the earlier rate, despite the fact that the maximum temperature in each tube rarely rose more than 1° C. from the thermostat reading in any of our experiments. It is thus evident that much of the change in velocity is not due to temperature rise, but further observation led us to question whether it was due to an increase in the rate of initiation of centres as suggested by Schulz and Blaschke.

In view of analogies in the kinetics, it seems reasonable to accept for methyl methacrylate a theory of polymerization similar to that substantiated by Schulz[4] for styrene. Thus, if C is the catalyst concentration, M the monomer concentration, and n the concentration of active centres, the rate of initiation of chains is given by k_1C, the rate of propagation by k_2nM, and the rate of termination by k_3n^2. This gives the steady rate of polymerization as $-dM/dt = k_2k_1^{\frac{1}{2}}k_3^{-\frac{1}{2}}MC^{\frac{1}{2}}$. If an increase in the rate of initiation (k_1C) is responsible for the rise in rate of polymerization of methyl methacrylate, then the chain-length of polymer should fall throughout reaction, for the average chain-length is given by $\overline{P} = k_2k_1^{-\frac{1}{2}}k_3^{-\frac{1}{2}}MC^{-\frac{1}{2}}$. In Schulz's data there is no evidence of such a fall during the period of increase of rate, notwithstanding considerable temperature increases; furthermore, in all our experiments (under practically isothermal conditions) we have invariably found an *increase* of chain-length of polymer throughout this period, even at 25° C. and 40° C., where catalyst decomposition must be inappreciable. A few typical results are given in Tables 1 and 2, illustrating our findings. In Table 1, $\overline{P}$ is an index of chain-length of polymer, being the linear extrapolation to zero concentration of the expression: (spec. viscosity in acetone / conc. of polymer, base mols. per litre).

TABLE 1. POLYMERIZATION OF UNDILUTED METHYL METHACRYLATE. TEMP. 25° C. 0·410 MOL. PER CENT Bz_2O_2. RATE APPROX. STEADY UP TO 12 PER CENT POLYMERIZATION.

Time (min.)	33	1238	2167	2255	2350	2548	2587
% Polymerization	0·3	12·0	—	33·1	37·5	—	47
Approx. rate polym., %/1000 min.	10	11	24	32	44	66	70
$\overline{P}$	—	15·6	17·6	—	19·8	20·3	—
Tube temp.	25·0	—	—	25·0	—	—	25·1

In Table 2 the square root law is illustrated, and it can be seen that the rise in rate was found to occur latest in the polymerization with the highest catalyst concentration.

TABLE 2. POLYMERIZATION OF UNDILUTED METHYL METHACRYLATE TEMP. 60° C.

Mol. % Bz_2O_2	Initial rate polym. %/min.	$\frac{\text{Init. rate}}{\sqrt{\text{Catalyst conc.}}}$	% polym. at start of rise in rate
0·0261	0·07	0·43	14
0·0950	0·14	0·45	16
0·412	0·28	0·44	21
0·775	0·37	0·42	26

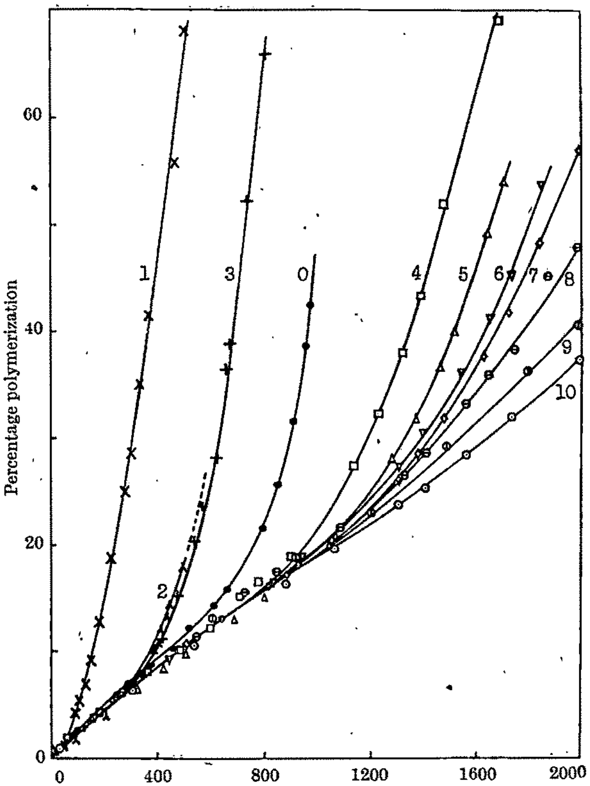
Further, with the same catalyst concentration, we found that higher temperature also caused a later rise. High catalyst and temperature are conditions for producing a low bulk viscosity of the polymerizing system for a given percentage reaction. This fact, together with our observations on the rise of chain-length throughout polymerization, suggested to us that increasing bulk viscosity is indeed essentially responsible for the rise in rate and chain-length, in that it decreases the rate 'constant' of termination k_3. For if k_3 decreases throughout polymerization, the rate and the chain-length will both rise. In this connexion Gee[5] has referred to the possibility of k_3 decreasing throughout polymerization.

As a critical experiment we polymerized methyl methacrylate at 40° C. with 0·0094 mol. Bz_2O_2 per litre in the presence of a series of diluents (see Fig. 1) each 40 per cent by volume. The diluents were chosen from good and poor solvents and also precipitants of polymethyl methacrylate, so that the bulk viscosity of each system at a given percentage polymerization would differ as greatly as possible. In order to obtain a measure of the extent of this variation in bulk viscosity, preparations were made, each of 0·93 gm. per cent, of a certain sample of polymethyl methacrylate in a mixture of 2 c.c. of monomeric methyl methacrylate and 2 c.c. of diluent (a small amount of hydroquinone was added to prevent further polymerization). Table 3 shows that the bulk viscosities were very different according to the nature of the diluent.

TABLE 3.

No. of diluent in Fig. 1	Nature of diluents	Bulk viscosity of preparation
1–3	precipitants	firm gel separating from clear liquid
4–7	poor solvents	thick sol or light gel
8–10	good solvents	thin sol

The accompanying graph summarizes the changes which took place during the polymerization of the various solutions of methyl methacrylate. None of the diluents was specially purified, and short induction periods were observed before polymerization started, presumably due to small amounts of inhibitor; the recorded curves are plotted from the end of each induction period. It will be seen that up to a certain stage in each experiment, the influence of all diluents was similar, but beyond this stage, the rate of reaction rose in a specific manner, in agreement with our views that with a poorer solvent and therefore greater degree of aggregation of polymer chains, the rise in rate should be more marked and occur earlier.



POLYMERIZATION OF DILUTED METHYL METHACRYLATE 40° C. 40% DILUENT (BY VOL.). 0·0094 MOL.Bz_2O_2/LITRE.

0, Undiluted monomer.
1, 2, 3, Precipitants of polymer: 1, butyl stearate; 2, heptane; 3, cyclohexane.
4, 5, 6, 7, Poor solvents of polymer: 4, amyl acetate; 5, *n*-amyl chloride; 6, ethyl acetate; 7, carbon tetrachloride.
8, 9, 10, Good solvents of polymer: 8, benzene; 9, chloroform; 10, methylene dichloride.

In our experiments with each diluent* we precipitated two samples of polymer: one during the initial period of slower reaction and the other after the rate of reaction had increased. In Table 4*a* values of the viscosity index of chain-length, $\bar{P}$, are given for the former period, and in Table 4*b*, for the latter.

A comparison of the two values for each diluent shows that the most marked increases of chain-length occurred for the poorest solvents, and scarcely any at all occurred for the best solvents; referring to the graph it can be seen that the poorest solvents gave the most marked rise in rate and the best solvents scarcely any at all. This parallelism between increase in chain-length and rate of reaction is exactly what we should expect, assuming the termination 'constant' k_3 to decrease with increasing bulk viscosity of the system.

TABLE 4*a*.

Diluent	Precipitants			Poor solvents				Good solvents		
Nos. (see graph)	1	2	3	4	5	6	7	8	9	10
% Polym.	–	4	13	10	13	12	12	13	12	12
$\bar{P}$.	–	13	18	12	13	13	12	13	10	12

TABLE 4*b*

% Polym.	71	15	62	70	55	55	62	52	35	38
$\bar{P}$	34	20	38	25	21	19	17	15	12	12

With diluents 1–3, the polymer precipitated as an opaque gel almost at the start of reaction, whereas with the other diluents, precipitation never occurred. We suppose that forces between polymer chains tend to produce association, while forces between solvent and chains act oppositely according to the solvent 'power'; thus, chain association can occur in a single-phase system or in an opaque gel according to diluent, causing a reduction of mobility of the active growing ends and therefore a fall in the rate of termination of chain growth.

It seems likely that variation of the rate 'constant' of mutual termination throughout polymerization is not confined to methyl methacrylate, though for this substance the effect may be particularly strong since there is probably little opportunity for kinking of the macromolecules[6], and thus the mobility of the growing ends of polymer chains may be more sensitive to constraints applied at remote parts. In the literature there are several instances reported of high rates of polymerization and chain-lengths, for example, with polyisobutene at low temperatures[7] and in some emulsion polymerizations[8], and it is possible that explanations may apply on the lines we have put forward. We ourselves have (incomplete) data suggesting that similar effects may occur to a lesser degree with vinyl acetate and styrene.

---

* It should be recorded that, in our experiments with diluents 4–10, about 1 per cent of polymer was present at the start. In order to minimize inhibiting effects of oxygen, reaction tubes were sealed, and monomer was kept *in vacuo*; at room temperature the monomer polymerized slowly.

ILLUMINATION AND VISUAL RANGE UNDER WATER

By DR. H. H. POOLE
Royal Dublin Society

IN a paper on illumination and visual range under water[1], R. Ruedy has given an account of measurements made with rectifier, or blocking-layer, photocells by some American and European workers during recent years, including particularly a summary of the important work done by Utterback and his co-workers in eastern Pacific waters, and by Clarke and his colleagues in the western Atlantic, and a useful bibliography which, however, does not include an important paper by Le Grand[2] or a paper by Atkins and Poole[3].

He has also attempted the rather difficult task of correlating the results so obtained with the visual observations recorded by divers, and given some account of photometric measurements made in Beebe's bathysphere, and of underwater photography.

In comparing the results obtained by different workers it is essential to consider the instrumental conditions under which they are obtained. It is always necessary that the cell should be enclosed in a water-tight case behind a strong window, which is generally horizontal so as to eliminate troubles due to the rotation of the photometer, and is turned upwards so as to measure the vertical downward illumination. Most workers nowadays place a diffusing glass above the window, so that the photometer may measure the light from a complete hemisphere falling on a horizontal surface; but this has not always been done, and without the diffusing glass the photometer, when submerged, is only sensitive to rays making an angle not exceeding 48° with the normal to the surface. This may, in certain circumstances, have an appreciable effect on the ratio of the illuminations recorded at different levels, and will certainly reduce the ratio of readings obtained with down-turned and up-turned windows, as a considerable part of the upward illumination must make large angles with the vertical. The absence of an opal glass will also increase the apparent loss of light at the sea surface, a quantity which is not easy to measure accurately except in smooth water.

The range of colour sensitivity of the photometer used is also important. Both red and ultra-violet are extinguished by sea-water very much more rapidly than green and blue; thus a selenium rectifier cell without colour filter (which is more sensitive than the eye to both ends of the spectrum) will, in uniform water, give a much greater extinction co-efficient near the surface than in deeper layers. The copper oxide cells used by Clarke in much of his work, being relatively less sensitive to the ends of the spectrum, do not show this effect to so great a degree. Utterback, who uses the selenium cell (which appears to be more stable than the other), has in most of his work limited the spectral range employed in each measurement by means of colour filters inside his photometer case interchangeable by an electromagnetic device. Atkins and Poole have also used the combination of colour filters with selenium cells in the waters off Plymouth. In the deeper layers—say below 20 m.—the absorption of the spectrum ends has rendered their effect negligible, and a cell without filter will only yield slightly different coefficients from those obtained with green or blue filters.

When allowance is made for any differences in the modes of measurement or of presentation used by different workers there is general agreement between their results. Thus, if, as is customary, we define the coefficient of extinction μ by the equation $-\frac{dV}{dx} = \mu V$, where V is the illumination on a horizontal surface at a depth x m., at a point 10 miles offshore, we might expect to find values for μ rather less than 0·4 for red light and rather more than 0·1 for blue and green. These figures correspond to reductions of illumination to 10 per cent in 5·7 and 23 m., respectively, this depth being equal to $2{\cdot}3/\mu$. As we move inshore μ increases, comparatively slightly for red, much more for green, and even more for blue, so that at an inshore station we might get values like 0·5, 0·3, and 0·4 for red, green, and blue respectively. In oceanic water, on the other hand, the blue and green coefficients fall, Clarke having recorded values about 0·05 for the blue-green light at considerable depths in the Sargasso Sea. The lower layers sometimes are more transparent than those above, so long as they are not too near the bottom, but frequently the water appears to be very homogeneous.

Utterback also made measurements with a selenium cell and a filter which reduced its spectral sensitivity to near that of the eye, and has given values of the illumination in foot-candles and in lux at various depths. By a curious slip, which might be overlooked and thus cause confusion to the reader, the reduction to lux has been made by dividing (instead of multiplying) the foot-candle values by 10·76.

Comparatively small changes in the value of μ will cause very large changes in the illumination at appreciable depths. Thus, a change from 0·08 to 0·12 (which might readily occur at any coastal station a few miles offshore) will reduce the light at 50 m. from 1·8 to 0·25 per cent of the sub-surface illumination. The lower of these values, however, would, on a bright summer day, still be equal to normal daylight about sunset.

The determination of the angular distribution of submarine daylight is not easy, but polar diagrams have been obtained in comparatively smooth and sheltered Swedish waters by Johnson and Liljequist. These workers found that the enhanced extinction of oblique rays caused a reduction of average obliquity with increase of depth. Whitney has also made such measurements in American lakes, and Atlantic waters, even as far off as the edge of the continental shelf, and considers that below 10–20 m. a balance between the effects of scattering and absorption maintains the average obliquity approximately constant. This view has also been put forward by Atkins and Poole, who used a cubical photometer containing six cells set in perpendicular directions. They found that, in the waters off Plymouth, below 10 m. there was no decided change in the ratio of the horizontal to the vertical illumination either with depth or with surface light or conditions, the average obliquity being about 38° corresponding to a mean illumination on a vertical surface about 25 per cent of that on a horizontal one. At a depth of 5 m. in bright sunlight this rose to about 67 per cent for a vertical surface in azimuth facing the sun.

Most workers are agreed that at a level well above the bottom the upward illumination ranges from about 2 per cent of the downward in very clear water to 5 per cent, or more, closer in shore. If we assume that the average obliquity is approximately independent of depth, we readily find from this that only 4–10 per cent of the light cut off in any thin layer is scattered back through angles greater than 90°. As scattering through smaller angles has such an effect in maintaining the average obliquity it must be much greater than this, which seems to indicate that the particles concerned are comparatively large compared with the wave-length of light.

Several workers, including Ruedy, Le Grand, and Whitney, have derived formulæ connecting the visibility of objects under water with extinction and scattering coefficients. One objection to these is the need for assuming some law of angular distribution of scattered light which may be far from the truth. The visibility of an object which is not too small depends on the ratio of its surface brightness, as seen, to that of the surrounding field. This ratio must differ from unity by an amount which is almost independent of the absolute brightness (provided this is not too small), and may, according to Ruedy, be taken as 2 per cent. The chief obstacles to visibility are (*a*) the reduction of the ratio of brightnesses by the addition to both of the daylight scattered by the intervening medium; (*b*) the reduction in absolute difference of brightness by extinction in the intervening medium, including the mixing of light from the object and field by scattering; (*c*) the possible reduction of illumination to such a degree that increased ratios are needed to ensure detection.

The extinction of red light reduces all objects to a green or bluish green hue a few metres under water. At greater depths, when the eye is dark-adapted, colour sensation is lost; visibility is, however, helped by the fact that the maximum sensitivity is then close to the wave-length which is best transmitted by sea-water.

It is evident that the distance at which an object is visible must vary greatly with its direction. A light-toned object, such as the Secchi disk, is probably most visible against the dark background of the water directly below the observer, although here the intervening scattering particles are more strongly illuminated than the object. A dark-toned object should be more visible in a horizontal direction, while the visibility of any object overhead must largely be governed by the degree of small-angle scattering. The presence of direct sunlight would introduce azimuthal asymmetry and further complicate the problem.

It would seem then that, pending further increase in our knowledge of the angular distribution of scattered light and of the resultant distribution of field brightness, it is difficult to estimate with certainty the visibility of a given object from measurements of light penetration alone.

THE FIGURE OF THE EARTH

A GEOPHYSICAL Discussion was held on August 14 in the rooms of the Royal Astronomical Society, when the subject dealt with was "The Figure of the Earth".

Sir Gerald Lenox-Conyngham opened the discussion with a statement of the values obtained by Airy, Everest, Bessel, Clarke and Hayford for the semi-axis major of the earth and for the ellipticity of figure. In attempts to eliminate so far as possible the effects of local deflexions of the plumb-line, Airy avoided arcs measured in mountainous country, while Everest used only the longest arcs available. The fundamentally important question arises as to whether these local deflexions may be treated as random errors; if so, it is appropriate to use the method of minimum squares in the reduction of the observation. This was the method employed by Bessel, and the fact that Airy did not use it suggests that he did not regard the deflexions as random.

An important development began with Waugh's suggestion to Archdeacon J. H. Pratt, of Calcutta, that he should calculate the gravitational pull of the Himalayas at various stations of the triangulation, with the view of correcting the observed latitudes. The calculated attractions were greatly in excess of those indicated by the observations, and led to Pratt's well-known theory of mountain compensation, and Airy's equally famous hypothesis of the "roots of the mountains". It seemed, then, that at moderate or at great distances the attraction of the mountains was for the most part compensated, and that deflexions observed well away from mountain ranges might be ascribed mainly to local causes, which would have a random effect on observations made at an evenly distributed set of stations.

Burrard's discussion of the accumulated Indian data in 1901 led to an important modification of this view. He found that the local deflexions showed systematic trends in directions parallel to the Himalayas; nor could their amounts be attributed to any system of mountains and their compensation. It was, therefore, incorrect to suppose that mountain attraction did not extend to any great distance, or to treat deflexions as random errors.

In 1909 Hayford published the results of his determination of the earth's axis and figure by a new method. Accepting mountain compensation as normally complete and assuming that below a depth of 113 km. there is hydrostatic equilibrium, he computed the effect of all topographical irregularities at each station of observation, and applied the result of the computation as a correction to the observed latitude, longitude or azimuth, as the case might be. There is, therefore, a difference between the smoothed geoid that Hayford was endeavouring to fit and that which had been dealt with in earlier determinations. Hayford, moreover, uses the data of the United States of America only; if a similar determination covering Australia could be made, the results would be of the highest interest.

Dr. R. Stoneley indicated how closely geodesy, astronomy and geophysics are interconnected. The connexion between the gravitational field of the earth and its geometrical form is noticed as soon as one uses a plumbline or spirit-level. It is natural to use as a reference surface a gravitational equipotential, and the equipotential that coincides with mean sea-level is termed the 'geoid'; since this is not a simple geometrical surface, it is convenient to use for reference a spheroid decided upon by international agreement. In a corresponding way gravity may be compared with a standard gravity formula. The relationship between trigonometrical work and the intensity of gravity is seen in Clairaut's well-known formula; the variation of gravity with latitude determines the ellipticity of the figure of the earth. It is assumed that the ocean is free from shearing stress, but no assumption is made concerning the distribution of density within the earth.

A theorem due to George Green shows that a knowledge of the external gravitational field does not determine uniquely the density distribution within the earth. None the less, some information of a general character is forthcoming from the theory of the earth's attraction; if A, A, C are the principal moments of inertia, M the mass, a the mean radius of the earth, and m the ratio of centrifugal force to gravity at the equator, then the ellipticity (ε) of figure is given by $J=3(C-A)/2Ma^2=\varepsilon-\frac{1}{2}m$. The number J can be found independently from the monthly term in the moon's latitude. The 'dynamical compression' $(C-A)/C$ is known from the period of the precession of the equinoxes, and with the preceding formula leads to the value 0·334 for C/Ma^2, whereas in a homogeneous earth the value would be 0·4. Thus, the earth must on the whole be centrally condensed. Likewise, a knowledge of J and m determines ε with great accuracy.

A further advance can be made if it is assumed that the earth is to a near approximation in hydrostatic equilibrium for forces of long period. The work of Callandreau and of Sir George Darwin then shows that, given ε, m, and the dynamical compression, the value of C can be found; the calculation indeed is so insensitive to the assumed law of density that the known ellipticity cannot be used to test a law of density that gives the correct value of C.

In spite of the restrictions imposed by Green's theorem, one can use observations of gravity over a restricted area to derive some information about the density distribution a little way below the surface. Some of the mathematically possible distributions involve negative masses, and in practice other methods, such as seismic exploration, are available to check gravitational measurements. Within these limitations, much scientifically and commercially useful information may be obtained.

The Astronomer Royal pointed out that the addition of the Callandreau-Darwin theory to the work of Clairaut brings in the assumption that the earth is in hydrostatic equilibrium throughout. Since the actual land surface is not a gravitational equipotential, the validity of this extra assumption requires critical examination. The justification is due to de Sitter, who assumed the earth to be in hydrostatic equilibrium from the centre up to a surface which he named the 'isostatic surface'; the undisturbed surface of the ocean was taken to be part of the geoid, and between these two surfaces the equipotential surfaces would not necessarily be spheroidal, nor would they necessarily be surfaces of equal density. If the hydrostatic condition were satisfied throughout, the upper surface of the (ideal) body representing the earth would be a surface which de Sitter calls the 'ideal surface'. The spheroid which is the best fit to the geoid he calls the 'normal surface'.

If the outer potential of a body which is symmetrical both with regard to an axis of rotation and to an equatorial plane is expanded in a power series in $1/r$ and it is assumed that the surface which is an equipotential surface is nearly a spheroid, the boundary conditions give for a body of the size, mass and angular velocity of the earth the relations

$$J = \varepsilon - 0{\cdot}0017287\,;\quad \beta = 0{\cdot}0086559 - \varepsilon,$$

where β is the coefficient of the term in $\sin^2\phi'$ in the formula for gravity at a point of the earth's surface; as already mentioned, the internal constitution is not involved in these formulæ. If we write H for the dynamical compression $(C-A)/C$, we obtain the equation $J/H = q = f(\varepsilon)$, which is applicable to the ideal surface, but not necessarily to the normal surface.

The definition of the normal surface as the spheroid of best fit to the geoid implies that in the development of both surfaces in a series of spherical harmonics the coefficients of the harmonics of degrees 0, 2, 4 are the same. It follows that for the normal surface J is the same as for the geoid. Writing for the ideal surface $J_1 = q_1H_1$, where q_1 is a function of ε, and for the actual earth $J = qH$, where $q = 3C/2Ma^2$, we have $J = J_1$, and it remains to find the difference between q and q_1. The computation made by de Sitter assumed that the actual earth differs from an ideal hydrostatic earth in having an excess of mass in the continents and a deficiency in the oceans; these mass anomalies are supposed to be isostatically compensated by a 'compensation' which is uniformly distributed throughout the material above the isostatic surface. If the suffix 1 refers to the ideal surface the results become:

$$(C-C_1)/C_1 = -0{\cdot}000{,}000{,}34\,;\quad H-H_1 = -0{\cdot}000{,}000{,}85$$
$$q-q_1 = -0{\cdot}000{,}000{,}03\,;\quad \varepsilon^{-1}-\varepsilon_1^{-1} = 0{\cdot}04,$$

so that the difference in the ellipticities is entirely negligible. If there were no isostatic compensation the difference in the values of ε would have been about two units.

Astronomical theory gives $J = \varepsilon - 0{\cdot}0017287 = q/P(A + B\mu')$, where P is the precessional constant, A and B are known with great accuracy from theory, and μ' depends on the ratio of the masses of the earth and moon. If, then, the assumption is conceded that the earth below the isostatic surface is in hydrostatic equilibrium (and there is evidence that this assumption is not strictly correct), this method gives the value of the compression with a smaller uncertainty than any other method.

Dr. E. C. Bullard discussed how far the values of $1/\varepsilon$ given by various methods agree with de Sitter's result. These values are:

Motion of lunar perigee	296·6 ± 1·2
Motion of lunar node	296·0 ± 1·2
Motion of moon in latitude	297·3 ± 0·9
Gravity observations	296·6 ± 0·5
Lunar parallax	294·7 ± 1·4
Triangulation (Hayford)	297·0 ± 0·5
Precession	297·24 ± 0·044
Nutation	297·61 ± 0·12

Of these determinations, the lunar parallax method depends on measurements at Greenwich and the Cape only, and may be suspected of serious systematic error. The mean of the first three is 296·7 ± 0·6; this astronomical determination, combined with that from gravity observations, gives 296·6 ± 0·4 (A). Accepting de Sitter's justification of the use of the precessional method, which involves the assumption of hydrostatic equilibrium, that method is capable of high precision, and the result differs from the preceding result (A) by 0·6 ± 0·4. This difference may not be significant, but if the difference is real, it implies stress differences of the order of 2×10^7 dynes/cm.^{2}, which are by no means unlikely.

Dr. H. Jeffreys recalled his attempt in 1941 to represent the observations of gravity over the earth's surface in terms of spherical surface harmonics. The problem is not statistically simple, for the existing observations are by no means uniformly distributed over the globe. In that determination, apart from the main ellipticity term, none of the coefficients was certain even as to sign. To carry through a least squares solution with twenty unknowns would involve very heavy computation, and therefore Dr. Jeffreys had now proceeded by a method of successive approximation. As a first step the normal equations were regarded as orthogonal, and only terms large compared with their standard error were retained. Departures from the international gravity formula were represented by

$$g-g_0 = \Sigma(a_{m,n}\,P_n^m \cos m\lambda) + \Sigma(b_{m,n}\,P_n^m \sin m\lambda).$$

The coefficients given by the first approximation, with their standard errors, were $a_{22}=4\cdot8\pm1\cdot3$; $a_{31}=6\cdot2\pm2\cdot3$; $a_{32}=2\cdot0\pm0\cdot6$, none of the others being as great as their standard errors. For a second solution he included a_{00} and also a_{20} (the main ellipticity term) and solved for the five coefficients by least squares. The result was: $a_{22}=4\cdot0\pm1\cdot4$; $a_{32}=1\cdot3\pm0\cdot7$; $a_{31}=4\cdot2\pm2\cdot4$; $a_{00}=2\cdot5\pm1\cdot9$; $a_{20}=-6\cdot1\pm5\cdot0$; and the coefficient b_{33} then had the value of $0\cdot46\pm0\cdot26$. The coefficient a_{22} indicates that the 'ellipticity of the equator' is genuine, but that the uncertainty is greater than that given by Heiskanen.

Compensated inequalities that would account for the harmonics a_{22}, a_{32}, a_{31} and b_{33} would be of amplitudes 5·2, 1·9, 1·9, 2·2 km. respectively. Now Prey computed in 1922 coefficients which give the representation of the earth's figure by spherical harmonics up to degree 16, and from his results it follows that there is practically no relation between mean height and gravity anomaly for inequalities with horizontal ranges of about 30°. Thus, the hypothesis of complete compensation must be abandoned. To explain the distribution of gravity an internal interface seems to be required, the height of which has a negative correlation with that of the outer surface. We have, in fact, strong evidence that isostasy is not exact, and are led to something of the type of Glennie's 'crustal warping'. The value of the reciprocal of the ellipticity of the earth derived from this investigation is 296·17, with a standard error of 0·68.

R. STONELEY.

OBITUARIES

Prof. F. E. Suess

NEWS has been received recently that Prof. Franz Eduard Suess, emeritus professor of geology in the University of Vienna, the son of Eduard Suess, died in Austria about a year ago, aged seventy-four. After many years on the Austrian Geological Survey, he occupied several academic posts before his appointment to the chair in Vienna in 1911. As an enthusiastic pupil of Becke, he was one of the first to make use of the petrology of metamorphism to interpret the history of rocks, a method he applied in grappling with problems of the crystalline massif of Moldanubia and studies of the deeper parts of mountain ranges where intrusions play an important part. Later, he integrated his opinions by enunciating a theory of mountain building through loading caused by the carriage of a moving 'creative mass' over a passive foreland. The ranges as they exist to-day result from the erosion of this structure. Fragments of the load left by chance can be distinguished from the loaded under-ground by the different grade of metamorphism they display, and a passage can be traced from the loaded to the unloaded part of the old foreland. It follows that the occurrence of a mass of crystalline schists in a mountain system is no evidence that they are older than fossiliferous sediments not far away in the unloaded region. Indeed, the sedimentary rocks in the 'creative mass' may be as old as the schists and gneisses formed below them. He regarded the Caledonian, and Variscan ranges of Europe, Asia and America as types of this orogenesis.

Suess was less prolific than his father, but he displayed an enviable erudition in contributions to a host of geological subjects. His lectures in Vienna were popular, partly on account of his masterly use of the German language, and partly because they covered the geological globe in a well-balanced conspectus supported by a background of documented facts. He was particularly attracted to Britain, where his father was born, and visited the Highlands more than once to compare their architecture with that of the Caledonian masses he knew so thoroughly near the Danube. He contributed papers in English on the thorny problems of the structures of the Scottish Highlands, and they provide a welcome variety in a rather mystic literature.

Though somewhat crippled in later years, Suess was surprisingly active, and in pursuit of his science he would walk long days amidst the woods of the Wiener Wald or on his own particular ground not far from the Danube, over the Scottish moors in their less pleasant moods, or brave the winter frosts of the Bushveldt and sleep with only a cloak between him and the stars at an age when such expeditions would dismay most men.

Suess was an LL.D. of the University of Glasgow and had a large circle of friends in Great Britain. He had a discriminating taste in art and music, in both of which he was no mean performer. The former rendered his field notebooks models of their kind as his skilful, truthful pen recorded pictorial evidence unbiased by theoretical distortion and furnished illustrations of field facts in a way that few can hope to do even with the aid of a camera. In the latter, his piano was near his study and upon it he would discourse in a most versatile fashion. Like many an Austrian he loved Mozart and Schubert, Beethoven and Wagner, but besides he was tremendously attracted by the unexpected harmonies of Richard Strauss. He had an unusual knowledge and appreciation of the whimsicalities of Gilbert and Sullivan. He attracted around him a large circle of students and friends who used to meet once a week in one of the parks near the Danube during each summer. To those who knew him he was ever genial and as a man hospitable to a fault.

J. V. HARRISON.

Mr. E. A. Nahum

MR. E. A. Nahum, a research worker in the Cavendish Laboratory, was killed in Cambridge during a recent air raid.

Nahum, who belonged to a Manchester family, was educated at Clifton College and at Pembroke College, Cambridge, to which he went with an Open Exhibition in 1936. He read for the Natural Sciences Tripos and obtained a first class in Part I and in Part II (Physics). He returned to Cambridge with a Goldsmith senior studentship in 1940 and began work on the cyclotron. The Cambridge cyclotron had not long been installed, and as most of the senior nuclear physicists were away, it says much for the young research workers that they not only kept it in running order but also obtained material for four very comprehensive papers on the deuteron bombardment of the heavy elements. In the last two of these, with R. S. Krishnan, which appeared in a very recent number of the *Proceedings of the Royal Society*, the first quantitative measurements were made of the reaction yields, which made possible detailed comparison of experiment with results predicted by the present theory of the interactions of deuterons with heavy nuclei.

Nahum was known to many as a young scientific worker of great promise, but students throughout the world will remember him as a leader of the anti-Fascist movement in the universities. His student life in Cambridge coincided with the struggle of the Spanish people against Fascism and he was the principal leader in building up the student anti-Fascist movement in Great Britain. After David Guest and John Cornford were killed fighting for the Spanish Republic, Nahum took the place of the latter as leader of the Communist Party in the University.

During this period he spent vacations in Paris working as a leading member of the committee of the World Student Association and became known to thousands of foreign students. In his third year, as president of the Cambridge University Socialist Club, he led the struggle among students against non-intervention in Spain, Japanese aggression and the Munich policy of appeasement. In the same year he obtained his first class in Part II Physics.

In subsequent years he continued his work among students both in the National Union of Students, as chairman of the Science Faculty, and as chairman of the University Labour Federation.

In his short life he never failed to put into action his belief that the universities must not isolate themselves from the life of the community and that university people have a vital interest in the progressive movement. At meetings called by the University Labour Federation in different parts of the country, students are pledging themselves to work, train and fight against Fascism as never before as the greatest tribute they can pay to the memory of Ram Nahum. J. D. BERNAL.

NEWS and VIEWS

Centenary of Sir James Dewar

ON September 20 occurs the centenary of Sir James Dewar, one of Great Britain's greatest experimentalists, occupying as he did for forty-six years the chair of chemistry at the Royal Institution and for thirty-six years guiding its destinies both by his position and his discoveries. Dewar added greatly to the lustre of the Institution, and by his many investigations, especially those on the liquefaction of gases and the attainment of high vacua, gained for himself a place among the leading chemists and physicists of his time. Born at Kincardine-on-Forth, he studied under Playfair at Edinburgh and Kekulé at Ghent, and at the age of thirty-three was made Jacksonian professor of experimental philosophy at Cambridge. Two years later he was chosen to succeed Gladstone as Fullerian professor of chemistry at the Royal Institution and after another ten years was made superintendent. The year he went to Albemarle Street had seen the experiments of Cailletet in France and of Pictet in Geneva on the liquefaction of the so-called permanent gases.

Following in the footsteps of his great predecessor, Faraday, Dewar in the early eighties began his own researches on gases which were to lead to many striking results. He first publicly exhibited liquid air, he obtained liquid oxygen and then liquid hydrogen in considerable quantities; in 1892 he invented and freely gave to science and the world the Dewar vacuum flask and in the early part of the present century discovered, as H. E. Armstrong said, "the marvellous power of charcoal to absorb gases at low temperatures " which " will render the period of 1900 to 1907 ever memorable". But Dewar's studies on gases, low temperatures and high vacua are but a part of his researches, which ranged from water to explosives, from atomic weights to spectroscopy, from the properties of soap bubbles to the temperature of the sun. He was elected a fellow of the Royal Society when he came to London in 1877, and lived to receive honours from scientific bodies at home and abroad. In 1904 he was knighted by King Edward. Above all else the welfare of the Royal Institution was his great ambition and anxiety, and after his death which took place on March 27, 1923, a bronze plaque portrait of him was placed on the staircase of the Institution he had served so long and so well.

Sir James Ivory, F.R.S. (1765-1842)

JAMES IVORY, the Scottish mathematician who died at Hampstead a hundred years ago on September 21, had the distinction of being among the first to introduce into Great Britain those methods of mathematical analysis which, from the time of Leibniz and the Bernouillis, had been gradually developed on the Continent. The only mathematical appointment he held was that of professor of mathematics at the Royal Military College then housed at Marlow, in Buckinghamshire. This post he held from his thirty-ninth to his fifty-fourth year. The son of a Dundee watchmaker, he was born in 1765, studied for six years at St. Andrews and Edinburgh and was then, in 1786, appointed a teacher in a school at Dundee. In 1789 he abandoned teaching to become partner in a flax mill, and it was on the dissolution of the partnership in 1804 that he came to Marlow. He gained a wide reputation for his mathematical and astronomical papers in the *Philosophical Transactions of the Royal Society*. He received several medals, including the Copley Medal of the Royal Society, and with several other men of science was knighted in 1831. He was a corresponding member of the Paris Academy of Science.

Soviet Scientific Films

A NUMBER of Soviet scientific films were presented at the Imperial Institute Cinema on September 12 by the Society for Cultural Relations with the U.S.S.R. in conjunction with the Association of Scientific Workers. The films, which covered a wide range of subjects, were of absorbing interest and high technical quality. They included novelties in Soviet scientific and technical practice besides the popularization of well-known facts for children and adult lay audiences. The former featured some excellent photographs of the Black Sea Express, a two-keeled motor sea-glider for passengers, with a speed of fifty miles an hour, Prof. P. Kapitza's miniature turbine for producing cheaply liquid oxygen, and a clever device for protecting workers at the forge from heat with a screen of running water which absorbs the infra-red radiation. An artificial fledgling, made by children, which automatically opens its beak and projects the food inserted by the unwitting mother bird into a bottle of formalin, enabling a complete register to be made of the foods consumed by various birds and their consequent effect on crops, gave an example of how children can contribute to scientific knowledge. A film illustrating the effect of energy expenditure on blood circulation and showing the function of the spleen, and a clear exposition of Lena Stern's method of treating shock extended the programme to the field of medicine.

The final film, "Experiments on the Revival of Organisms", was undoubtedly the most impressive. After a brief and exceptionally clear pictorial explanation of the function of the heart and lungs, the film leads up from the artificial setting in motion of an individual organ, the heart, to the revival of a dog's severed head and finally to the revival of the animal itself, from which the blood has been completely drained off and the heart-beats and respiration of which had ceased for ten minutes. The blood is re-circulated by means of an artificial circulatory system, the 'autojector', the deceased animal heaves its first sigh, heart-beats and respiration begin to register, and, after a short time, the autojector is disconnected and life proceeds. Within a few days the dog is its normal self again and, as the film shows, "lives happily ever after". The producers are to be congratulated on the skill and beauty of this film, which, while maintaining full scientific clarity throughout, nowhere offends the æsthetic senses, opens up an unlimited perspective of scientific advance and cannot fail to instil into the most unimaginative minds a profound respect for scientific effort and achievement. The commentary to the films was prepared by Prof. J. B. S. Haldane.

Mr. Arthur Elton, in his opening remarks, dwelt on the systematic way in which the popularization of science is treated in the U.S.S.R. and stressed the necessity of a scientific approach on the part of the whole population in the interests of the maximum war effort. This view was expanded in an introductory lecture by Dr. M. Ruhemann, who pointed out that, in the U.S.S.R., the diffusion of scientific knowledge and a scientific approach to life has always been considered a matter of urgent necessity, whereas we have tended rather to regard it as a luxury. Reviewing Soviet methods of popularizing science, in books, newspapers, in children's clubs and on the collective farms, he directed attention to the lack of scientific and technical knowledge among young people in Great Britain, due to a large extent to an antiquated school curriculum, and to the tragic consequences which this is bound to have on the efficiency of our Forces in a highly mechanized war. Mr. D. N. Pritt moved a vote of thanks to the speakers and the promoters of the meeting, which was so well supported that large numbers had to be turned away. A repetition of the exhibition is being considered.

Imperial Institute

THE extensive facilities available at the Imperial Institute, London, S.W.7, for the rapid supply of technical information relating to the trade, occurrence and utilization throughout the world of all kinds of raw materials, and the scope of the intelligence service are not so well known as they should be. The Institute's staff includes tropical agriculturists, chemists, chemical technologists, economic botanists, economic geologists, mining engineers, mineralogists and statisticians, and, when desirable, the Institute seeks the advice of members of its fifteen consultative committees. Further help is also afforded by numerous trade contacts. The Institute also has an extensive reference library and a technical index covering most of the relevant trade and scientific publications issued during the past thirty years. The Institute can deal with inquiries relating to sources of supply of, and other information relating to, raw materials and semi-manufactured products whether of animal, plant or mineral origin in all countries, cultivation of crops and the soil and conditions under which they have to be grown, methods employed in mining, smelting and dressing minerals for the market, and so on. Analysis and testing of samples of raw materials is undertaken in the laboratories of the Institute. Inquiries should be made in the first instance to the Intelligence Section of the Plant and Animal Products Department or of the Mineral Resources Department, according to the nature of the subject concerned. No charge will be made for services to Departments of the United Kingdom Government or other Governments of the Empire contributing to the general funds of the Institute unless a particular inquiry involves a volume of work so great that it cannot be undertaken by the existing staff.

The Rockefeller Foundation

DURING 1941 the Rockefeller Foundation appropriated more than nine million dollars for public health, medical sciences, natural sciences, social sciences, humanities and a programme in China. The work in public health received the largest appropriation—2,450,000 dollars. Medical sciences came next with 2,120,000 dollars. The Foundation distributed 1,938,300 doses of yellow fever vaccine to the United States Government and 1,972,386 doses to Africa. Including the total sent to India, Brazil and Singapore, the Foundation gave a grand total of 4,260,680 doses of its own manufactured yellow fever vaccine. The Paris office of the Foundation closed in July 1941, and there are now no Foundation representatives on the Continent of Europe, though an office is being maintained in London. The Far Eastern office was removed from Shanghai to Manila late in 1940. Important studies are being carried out in Malta, in Trinidad and on the Burma Road.

Detection of Cracks in Engineering Materials

A VALUABLE development in the use of fluorescent light is its application to the detection of flaws or cracks in engineering materials, and a demonstration showing its effectiveness was recently given by Colloidal Research Laboratories, 66–70 Petty France, London, S.W.1. Their 'Glo-Crack' system, as it is named, marks a great advance on existing methods and makes the detection of the least visible form of crack as nearly as possible a certainty. The articles to be examined are first immersed for a short period in a hot bath of fluorescent material. They are then transferred to a second bath containing a solution which removes all the fluorescent material except that which is entrapped in any flaws or cracks. This part of the process is very much the same as the familiar one of degreasing and, as a secondary advantage attached to the new process, it may be mentioned that the hot bath is actually an efficient degreasing agent.

After this preparation, each article is examined under ultra-violet light and every small flaw or crack glows with the characteristic colour while the remainder of the specimen remains dark. In this way a crack, no matter how fine, can scarcely escape detection, and this is attained without severe eye-strain or mental fatigue on the operator. Other advantages which the demonstration exhibited are its applicability, without staining or the necessity for after-treatment, to all metals and to many other materials, its simplicity and cheapness of operation, and the quickness with which the process can be carried out, even on mass-produced articles.

While the normal technique is that of dipping in the fluorescent bath, this can be varied to suit special cases. An exhibit of special interest was a flaw in the interior of the base of an aeroplane propeller blade. The hole had been sprayed with the fluorescent solution and after being washed out, the insertion of a black lamp showed the flaw glowing clearly with fluorescent light. This obviously valuable scientific process was shown in its adaptation to the practical requirements of engineering, but its great possibilities suggest a much wider field of application both in scientific investigation and industrial development.

Magnetic Crack Detectors

AN article in the *Electrical Review* of August 28 describes a magnetic detector used to facilitate crack detection in motor and aero-engine parts. While radiographic methods of crack and blow-hole detection possess undoubted advantages when the flaw lies below the surface, for superficial cracks and defects as much as $\frac{1}{4}$ in. below the surface, the magnetic crack detector offers advantages in the speed and economy of its application. The general principles of the method have been described in the *Electrical Review* of April 4, 1940. They consist briefly of subjecting the part under test to a magnetic field and applying a magnetic powder, or a liquid medium containing such powder, to the suspected surface, so that any polarity due to a crack is rendered visible to the eye by collection of the magnetic particles over it.

The crack detector described, known as the 'Magnaflux' (Equipment and Engineering Co., Ltd.), possesses the special feature of sliding laminated pole tips between which the object is mounted for inspection. A few seconds only are needed to adapt them to objects of almost any shape by merely sliding the laminations up to the contour of the specimen. A further feature is that means are provided for controlling the magnetizing current, which is important on account of the need for avoiding supersaturation, or insufficient saturation. There is an optimum degree of magnetization giving the most readily seen and crisply defined crack outlines. Demagnetization of the tested parts is effected by laying the objects on a horizontal platen magnet, or subjecting them to an A.C. field: demagnetization is practically instantaneous.

Electricity in a Beet-Sugar Factory

B. SMITH has described (*J. Inst. Elec. Eng.*, 89, Pt. 2, No. 10; Aug., 1942) the application of electricity in the treatment of sugar beet through all the stages to the ultimate production of pure sugar. Although many factories in Great Britain have applied electricity in the best manner possible within their limited expenditure, yet both in the factory and in the laboratory there still remains much room for further improvement. For example, individual drives could be installed in many places where at present one large unit and line shafting now exist, and provided they are suitably interlocked—especially where elevators and conveyors work in conjunction—would prove a great advantage. Again, the sugar house should be equipped with the best type of sugar-spinning centrifugals. Much has been done by the manufacturers in conjunction with the users to improve this class of machinery.

The Electrified Cane-Sugar Factory

IN a paper on this subject (*J. Inst. Elec. Eng.*, 89, Pt. 2, No. 10; Aug., 1942) L. B. Whitaker deals with some of the considerations relating to total electrification of such factories, with special reference to the factory at Gray's Inn, Jamaica. Reasons are cited for the slow adoption of the totally electrified sugar factory in the British Empire as compared with other parts of the world. A brief general description of the processes involved is then given, advantages and disadvantages being discussed and some comparison drawn with steam-driven plants. The necessity of having a sugar factory specially designed for all-electric drive is then stressed, and details are given of the general layout of such a plant to obtain the maximum benefits of total electrification. The most suitable type of apparatus to employ is discussed, including notes on power-factor correction and maintenance routine. The paper concludes with examples of typical power consumption and cost of generating current.

Rural Electrification and Research

AN article by A. G. H. Dent (*Electrician*, August 21) surveys the necessary and probable trend of rural electrification and research in Great Britain during the post-war construction period. The author opens with a reference to the national education in food values and uses. The national neglect of agriculture is ended, and any positive reconstruction policy must incorporate broad measures of industrial decentralization of agricultural development and of food—or health-education. The article proceeds to define the position and responsibility of the public utility company in such a scheme, stressing that the words 'public utility' imply usefulness to the public as a national service forming an essential part of the social structure.

The recent introduction into farming of a minimum wage for agricultural labourers of £3 per week is cited as an incentive for electrical methods of carrying out farming operations on a continually increasing scale; with such a demand will come the need for electrical apparatus and machinery for doing the work. During the last few years, root cooking by electrical methods has been successfully employed, while the electric wash boiler has found application in the boiling of potatoes. There appears to be a demand for a cheap, low-loaded apparatus, of 1–3 kw., designed especially for root cooking. Bottle washing, herb drying, and the provision of hot water for feeds and mashes are also quoted as more recent uses of electricity in farming.

Mention is made of a G. E. C. (U.S.A.) experiment in which fruit trees and seeds are bombarded by X-rays in an attempt to improve the size, quality and flavour of the fruit. It is thus evident that a technique may be developed for the more intensive electrification of agricultural processes and that changes may be brought about gradually in farming methods.

Epidemics in English Villages

In his Milroy Lectures for 1942 before the Royal College of Physicians (*Univ. Leeds Med. Magazine*, 64, 12; 1942) Dr. W. N. Pickles, the energetic medical officer of health for Aysgarth in Yorkshire, chose for his subject "Epidemic Disease in English Village Life in Peace and War". He makes a strong appeal to country doctors to follow his example in keeping diligent records, preferably in chart form, of various epidemics in their districts such as influenza, scarlet fever, measles, German measles, mumps, acute rheumatism and cholera, summer diarrhœa, epidemic jaundice and epidemic myalgia, the last being a disease which Dr. Pickles was one of the first in Great Britain to describe. Contrary to what he had expected, Dr. Pickles has so far not found that war conditions have caused an increase of epidemic disease, although village life has changed to some extent owing to the immigration of town children. Since the outbreak of the War there has been no scarlet fever or infantile paralysis in the Aysgarth district and only a few cases of measles and cerebrospinal fever, while the only epidemic due to an evacuee was one of jaundice, of which there were fourteen cases. The chief sources of annoyance were impetigo, vermin and scabies, but these were soon brought under control.

Public Health Research

According to an annotation in the *Journal of the American Medical Association* of July 25. the Health Research Institute of the City of New York will receive a million dollars a year for ten years for researches on public health. The City and the Institute, which is a non-profit scientific institution, have entered into a contract which came into effect on July 1 and is automatically renewable for similar periods. The money is to be used to carry on fundamental medical research under the direction of a research council composed of authorities in medicine, biology, physiology, nutrition, public health and related subjects. Under the contract the services to be rendered by the Institute will include the following: (1) investigations into the control of diseases such as influenza, poliomyelitis, arthritis, degenerative diseases and general physiological problems; (2) engagement in laboratory experimentation in order to develop better and more economical biological products and improved technical procedures for use in controlling diseases and epidemics; (3) aid to the director of the Bureau of Laboratories of the Department of Health in matters involving public health research.

Electronic Relay Control

One of the more useful by-products of the rapid development of radio technique is the use of thermionic valves as relays of negligible input power, freedom from contact troubles and practically instantaneous operation. These features are utilized to the full in the series of devices and instruments now marketed by Messrs. St'r Electronic Controls, 76 Cavendish Road, London, S.W.12, as the result of considerable experience. One of the devices comprises an electronic relay operating on the usual alternating current supply of 230 volts 50 cycles per second, and giving an output of either 200 or 1,000 watts, the latter being capable of starting a ½ h.p. motor on 230 volts A.C. supply. This operation is obtained with no time delay, and with an effective current through the regulating contacts of about two microamperes. The same instrument may also be used for high speed machine timing operations, or the regulation of temperature, pressure, humidity or hydraulic flow. As an example, a laboratory type of constant temperature bath is available, in which the accuracy of regulation is better than ± 0·01° C. Another type is a liquid level regulator, with no float or other moving parts within the container; this is particularly suitable for use with electrolytes, and the electrodes may be a fraction of an inch apart or several feet from each other. An electronic 'stop-watch' records time intervals up to 2,000 seconds in intervals of a fifth of a second. It seems likely that these and other similar devices will find widespread application to laboratory and industrial processes.

Ice on Conductors

From time to time overhead lines fail by mechanical overstresses alone, due to excessive ice loading. These deposits have been widespread, and in view of the severity of recent winters, J. McCombe (*Elec. Rev.*, Aug. 21) suggests that an amendment of the Electricity Commissioners' Overhead Line Regulations El. C. 53 (revised) is necessary. The suggestion is supported with the following observations and criticisms. In the first place the selection of a different basic loading for high- and low-voltage lines is very much open to criticism since wind and ice loading are functions of exposure and altitude and definitely not of line voltage or conductor size. Deposits on overhead lines in exposed places are more or less constant irrespective of voltage. If a better standard of construction is desired, then the more logical method would be to adopt a higher factor of safety of erection. Low-voltage lines with the same ice coating will always have a greater security owing to the shorter span-length employed.

In the Regulations referred to, assumptions have been made to simplify the problem of ice loading. The ice is taken as forming a true annulus around the conductor. The author's observations are that ice is never deposited evenly or uniformly, either in wind or calm. Its nature depends to a great extent on the prevailing wind and atmosphere. In wind, ice tends to form thickest in the leeward side of the conductor. Windage helps to build up ice deposits, in as much that each particle of sleet imparts kinetic energy due to the wind and is responsible for the heavier deposits being driven to leeward. It probably also accounts for the different ice densities encountered on overhead lines. The worst deposits, however, are due to fog, not to wind and sleet. The heaviest deposits result from fog in the presence of a light wind, when icing is worst on the windward side of the conductor. It is thought that the fog precipitates ice as soon as it finds a metal anchorage. Such ice usually has a heavy, solid core, but becomes fuzzy and less dense on the surface. The article concludes with the suggestion that grading or zoning of the country, according to climatic conditions, would be advantageous, and by way of illustration describes the way this is done in the U.S.A.

Recent Earthquakes

According to the Swiss Seismological Bulletin for June 1942 just received from Zurich, twenty-one earthquakes were registered by the seismographs at

Chur, Basel, Neuchâtel and Zurich during the month. The following have not been mentioned previously in the columns of NATURE: An earthquake on June 1, registered at Chur at 09h. 04m. 11.7s. U.T., which came apparently from an epicentre near the Presse Griechenland. The earthquake of June 20 which registered at Chur at 14h. 42m. 01·8s. U.T. came probably from Trentino, Valle Judicaria, in Italy. The earthquake of June 25, which registered at Chur at 22h. 13m. 13·9s. U.T., came apparently from an epicentre at Mürtschenstock, Kt. Glarus, Switzerland, and was felt with intensity IV–V.

The earthquake of August 24 in Peru (NATURE, September 5) was registered at Kew at 23h. 03m. 36s. U.T. and attained a maximum ground amplitude at Kew of 1,520 μ. The earthquake of August 27 in the Balkans (NATURE, September 5) was also registered at Kew at 06h. 18m. 16s. U.T. and attained a maximum ground amplitude at Kew of 210 μ.

THE United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association has determined the epicentres of several recent earthquakes near South America. These determinations have been based on instrumental reports from fifteen observatories. Altogether there are seven shocks, six being near latitude 0·8° N., longitude 80·5° W., which is just off the coast of northern Ecuador in South America. The dates of the shocks were all in July—4 (2), 5, 7, 8 and 12. The seventh earthquake was on July 8, and its epicentre was near latitude 25·5° S., longitude 79·5° W., which is in the bed of the Pacific Ocean off the coast of Chile, and north-east of the islands of San Felix and San Ambrosio.

Data for Radio Engineers

A SMALL publication (Reference Data for Radio Engineers. Pp. 60. Standard Telephones and Cables, Ltd., 63 Aldwych, W.C.2. 2*s.*) should find a ready appeal to all radio engineers, whether they are engaged in replacing a small fixed resistor in a wireless receiver or a piece of laboratory apparatus, or working on the design of a world-wide radio telephone service. The data included in this booklet have been selected as a result of the experience of engineers engaged in the development of radio communication systems during the past twenty years. A very wide field is covered including electrical and mechanical constants, properties of materials, circuit theorems, impedance operators, abacs and other data of everyday utility to those conducting design and development work. A noteworthy inclusion is that of wave propagation curves summarizing the best technical knowledge available at an international conference held in 1938. The above material is supplemented by a generous amount of mathematical formulæ, and the usual tabulated quantities up to and including tables of Bessel functions, the need for which has grown so rapidly of recent years in connexion with phase- and frequency-modulation systems. Since the effectiveness of any communication link, land-line or radio is nowadays expressed in terms of the ratio of the wanted signal to the noise-level, it is only natural to find a few pages devoted to noise determination and measurement, and charts showing the relationship between the European and American units in the standardization of noise measurement. The reference book is a commendable effort in a comparatively new field.

Announcements

SIR ROBERT RENWICK has been appointed to the newly created post of Controller of Communications Equipment in the Ministry of Aircraft Production, and will become a member of the Aircraft Supply Council. He will be assisted by Sir Robert Watson Watt, as vice-controller. Sir Robert Renwick has also been appointed controller of communications in the Air Ministry, where Sir Robert Watson Watt will continue to hold the appointment of scientific adviser on telecommunications. These arrangements will ensure still closer co-ordination between the two departments in this important field.

THE following appointments in the Colonial Service have recently been made: P. H. Richards, agricultural officer, Nigeria; B. J. Silk, agricultural officer, Gold Coast; M. P. Ford, veterinary officer, Kenya; A. E. G. Markham, veterinary officer, Kenya; C. O. Oates (agricultural officer), senior agricultural officer, Kenya; K. Wallis (government analyst, British Guiana), government chemist, Uganda.

ARISING out of a recommendation made to the Council of the British Association at the conclusion of the Conference on European Agriculture, a committee has been appointed, under the chairmanship of Sir John Russell, to collaborate with the Allied Technical Advisory Committee on scientific problems connected with the post-war reconstruction of agriculture in the devastated and oppressed areas of Europe. The Council of the Association has also appointed a committee, under the chairmanship of Dr. Dudley Stamp, with the view of strengthening the applications of science (for example, geology, geography, ecological botany and zoology, soil science, agricultural economics, and forestry) to rural planning in particular.

THE first lecture in the autumn programme of the thirtieth annual series of Chadwick Public Lectures will be given at the Royal Society of Tropical Medicine, 26 Portland Place, London, W.1, on October 6, at 2.30, when Sir Leonard Hill will lecture on "The Inter-Relation of Clothing and Shortage of Fuel in Matters of Health". Sir William J. Collins, chairman of the Chadwick Trustees, will preside, and shortly before the lecture (at 2.15 p.m.) will present the Chadwick Medal and Prize to Mr. Wilfred Glyndon May of University College, London. Admission to all the lectures is free and tickets are not required.

THE Medical Research Council invites applications from medically qualified women for a studentship for training in methods of experimental psychology; preference will be given to candidates who have had some special training in physiology or neurology, or who have already had some experience in the use of research methods. The studentship will be tenable for six months, during which the holder will receive training under the direction of Prof. F. C. Bartlett at Cambridge. Payment will be at the rate of £350 per annum and the student will be expected to give her whole time to the work. Further information can be obtained from the Secretary, Medical Research Council, c/o London School of Hygiene, Keppel Street, London, W.C.1, to whom application should be made by October 5.

LETTERS TO THE EDITORS

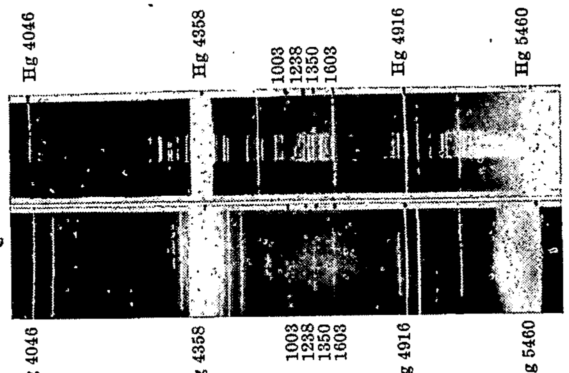
Raman Spectrum of 1,3,5-Triphenyl Benzene

In two previous communications[1] one of us has reported investigations on the structure and Raman spectra of some of the polynuclear aromatic compounds, and we have also submitted elsewhere[2] details of the results on the *ortho-*, *meta-* and *para*-diphenyl benzene. In continuation of those investigations we have studied the Raman spectrum of symmetrical triphenyl benzene, in solution in carbon disulphide and carbon tetrachloride and also in other suitable solvents. The melting point of this substance is fairly high and it presents the difficulty that as its temperature is raised to its melting point it tends to become unstable and decompose.

Two of the spectrograms of the substance taken in solution using a Füess glass spectrograph and some suitable filters are reproduced here. The substance is highly fluorescent under the total radiation of the mercury arc, but it will be seen that owing to the large diminution in the intensity of the 4046 A. group of mercury lines, the fluorescence is not appreciable and the background is quite clear. The frequencies observed and found common in both carbon disulphide and carbon tetrachloride solutions are at 3046(1), 2036(4) ?, 1603(8), 1496(1), 1350(6 br.), 1238(4), 1045($\frac{1}{2}$), 1003(10), 603(1), 406(1), 234(1), 170(5), 146(6) and 87(4 br.) cm.$^{-1}$ respectively (intensities are given in brackets). A few more lines have also been observed in acetic ether and chloroform solutions at frequencies, 2987(4), 1458(5) and 384(5) cm.$^{-1}$. As the excitation of these lines was due to λ 4358 alone, it is expected that the assignment is free from error.



a, triphenyl benzene in CS_2 solution ; *b*, triphenyl benzene in CCl_4 solution.

The most significant points of resemblance were found with the spectra of *m*-diphenyl benzene, which consists of three benzene rings, two of these being substituted in the third in the meta position. Symmetrical triphenyl benzene consists of four benzene rings, three of which are substituted in the fourth in positions 1, 3 and 5. Loss of any one of these three benzene rings converts the substance into *m*-diphenyl benzene. The close agreement between the majority of triphenyl benzene frequencies and those of *m*-diphenyl benzene will be found in the following *m*-diphenyl benzene frequencies obtained by one of us[3] and S. Abdul Aziz. These frequencies are at 1607(4), 1350(0), 1241(4 br.), 1039(1), 1000(10), 611(3), 406(3), 238(3 diff.), 151 (2 diff. and br.) and 80 (4 diff. and br.) cm.$^{-1}$.

The strongest frequency of triphenyl benzene, observed at 1003 cm.$^{-1}$, is found equally strong in *m*-diphenyl benzene and is also present in all the other compounds of this series. But the marked dissimilarity is that the very strong line at 1309 cm.$^{-1}$ observed in *m*-diphenyl benzene and almost equally strongly in all the other compounds of this series is found to be completely missing in this compound. The other very marked difference is that the stronger frequency of the doublet at 1597 cm.$^{-1}$, also found in all the compounds of this series, is not observed in triphenyl benzene. A few of the other lines observed here are also present in benzene and are therefore due to the vibration of the benzene ring. The line at 88 cm.$^{-1}$ is due to the molecule itself, although the frequency is very low as the substance was studied in dilute solution.

These results are expected to give a clue to the symmetry and nature of the disposition of the substituted phenyl groups of this compound.

Further work is in progress, and a discussion of the bearing of these results on the nature and symmetry of the benzene rings of this compound will be published elsewhere.

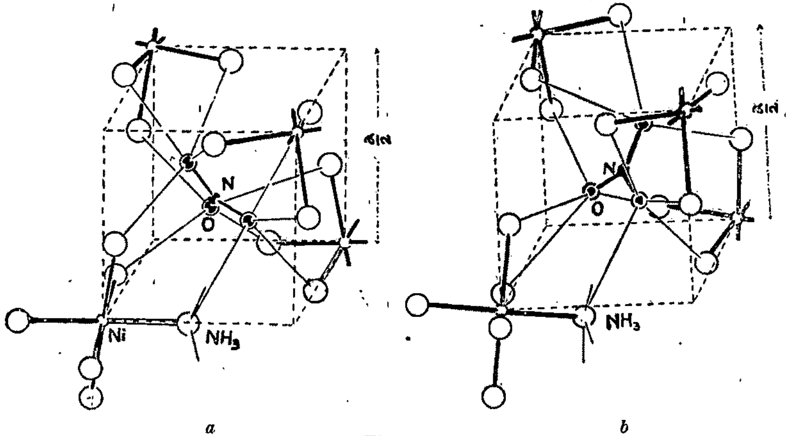
Formation of a Double Crystal Aggregate and the Structure of the Intermediate Temperature Modification of $Ni(NO_3)_2.6NH_3$

About five years ago I made an X-ray study in Manchester, under Sir Lawrence Bragg's kind supervision, of the structure of $Ni(NO_3)_2.6NH_3$ at different temperatures. Three modifications were observed and the structure of the room temperature modification was determined[1]. Attempts were made without success to find the structure of the intermediate temperature modification on the assumption that the structure had the symmetry (F43*m*, F43, or F*m*3*m*) shown by its X-ray photographs. It was not until three years had elapsed that an idea of the partition of a single crystal into a double crystal aggregate came to my mind, and hereupon a structure was obtained which can explain very naturally and satisfactorily all the X-ray intensity data of more than 300 reflexions. In view of the interest in the mechanism of the conversion from the room temperature to the intermediate temperature structure and in the formation of the double crystal aggregate, it is thought probably opportune to give a brief account of the work here.

The intermediate temperature modification of $Ni(NO_3)_2.6NH_3$ is obtained by cooling the crystal grown at room temperature by a stream of liquid air falling on it at a suitable speed. The modification belongs to the cubic system, like the room temperature modification; its structure also consists of flat triangular NO_3 and octahedral $Ni(NH_3)_6$ groups interlocking one another into a CaF_2 grouping. Unlike the room temperature modification, however, the NO_3 groups in the present structure no longer execute any abnormal oscillation, but assume either one of two alternative configurations roughly corresponding to the two extremities of an oscillatory NO_3 in the room temperature structure[1]. Now suppose that at the very beginning of the conversion of the modifications from the room temperature to the present, a particular NO_3 group in the crystal, owing to the loss by cooling of its oscillation energy, assumes one of the two alternative configurations. The change of the state of this NO_3 group will immediately bring about a modification of the configurations of its neighbouring NH_3 groups; the modification so caused then in turn makes the other neighbouring NO_3 groups assume the more probable of the two alternative configurations. These NO_3 groups then cause their own neighbours to change their positions, and the propagation of this process finally results in a structure which has the space group *Pa*3. If the NO_3 group which starts the conversion assumes the other one of the two alternative configurations, the resulting structure is the same as the one just mentioned, except that the orientation of the second structure, when looked at along a cube axis, differs by 90° from the first one. In Fig. 1 (*a*) and (*b*) are shown the alternative configurations of a NO_3 group the original configuration of which in the room temperature structure is shown in Fig. 1 in reference (1).



a *b*

Fig 1.

Now let us consider the conversion process taking place in the whole crystal. We first expect that the conversion must be started simultaneously and independently by a considerable number of NO_3 groups in the crystal, like the solidification of a melt being started by the growth of grains from numerous nuclei in the melt. However, the nuclear NO_3 groups here can assume only two possible configurations instead of any random orientation, the consequence of which is that the resulting crystallites, after the conversion is completed, must have their crystal axes confined to two mutually perpendicular directions, that is, the directions of the axes of the original single crystal. Furthermore, the external shape of the crystal is not changed. On these accounts, the spots on the oscillation photographs of this crystal appear as if they were reflected from a single crystal, except that each spot is a superposition of two reflexions *hkl* and *khl* on the photographs taken with the crystal oscillating about the [001] axis. Thus the symmetry shown on the photographs is not the actual symmetry of the structure. Since the crystal is neither a single crystal nor an ordinary polycrystalline mass, I tentatively call it a 'double crystal aggregate'. A schematic representation of a section of the aggregate perpendicular to the [001] axis is shown in Fig. 2.

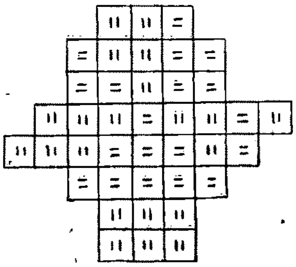


Fig. 2.

The discovery of the aggregate leads us to the following considerations:

(1) The determination of the space group of a structure must be made with due consideration of the possibility of the formation of an aggregate of double or even similarly defined triple crystal when the X-ray oscillation photographs used for the space group determination are taken with the crystal at a temperature different from the one at which the crystal is grown.

(2) It might be expected that the crystalline grains in some polycrystalline metals are really not single crystals but composed of aggregates of the preceding kind, if the metals cooled down at a moderate rate from a high temperature have their structures at the final temperature bearing a favourable geometrical relationship with their structures at the initial temperature. Since numerous new intergranular boundaries must exist within each aggregate we naturally raise the question as to the nature of these new boundaries. If they are of the same nature as the ordinary intergranular boundaries, we should expect a metal to be hardened by the formation of such aggregates. Since the formation is brought about by a mechanism (not necessarily involving any abnormal oscillations of some atom groups in the initial structure, of course) totally unknown before, and the resulting product of the formation is in a quite stable state, the study of this formation in metals would introduce a new type of hardening process in physical metallurgy. On the other hand, if the new boundaries differ in their physical properties from the ordinary ones, a study of this difference might add some knowledge to the understanding of the nature of the latter. Again, we might have the question of whether these new boundaries have anything in common with the boundaries between blocks of the mosaic structure of a crystal. Finally, I should remark that the new boundaries cannot be detected either by the etching and microscope method or by the X-ray method of the powder photograph.

A detailed account of this work will appear elsewhere.

I wish to express my sincere thanks to Sir Lawrence Bragg for his suggestion of this problem and for the keen interest he took in the work; also to Mr. P. Y. Hwang, who made the final adjustment of the parameters in the structure.

Mechanism of Metallic Friction

DR. BOWDEN and his collaborators[1] in their investigations on the mechanism of metallic friction need have little doubt that, under many of the conditions of load and speed used in practice, the local temperatures reach a high value. Very high local temperatures are attained in very short intervals of time, as those who have observed 'seizure' taking place between the cylinder or liner and piston in an internal combustion engine can testify. The opportunity of witnessing this occurrence is rare in modern engine design with closed crank cases, but in the days of the horizontal gas engine, with the open-ended cylinder and trunk type piston, high temperature, often a white heat, was frequently observed when 'seizure' took place.

Probably at that time before the days of ground finishes, 'seizures' on the test bed were a more frequent occurrence. The dimensional accuracy of the 'fit' allowances, in addition to the character of the wearing surfaces, which were finish turned and bored, contributed to this state of affairs. Engineers certainly relied very much more on 'running in' to establish satisfactory working surfaces. I recorded some observations on these matters in a paper before the Manchester Association of Engineers in 1916.

Examination of 'seized' surfaces of cylinders, pistons and rings showed 'flowed' failures, and I well remember our chief engineer in those days being profoundly convinced that such layers had been molten and consisted of metal melted during the 'seizure'.

Shape of Subjective Space

IN a discussion of blind spot phenomena, Bartley[1] raises the question as to whether points subtending equal visual angles are subjectively equally separated, and suggests that the form of subjective space is related to the density of the rods and cones in the retina.

A theory that each sense-cell (or rather each fibre of the optic nerve, where more than one cell converge on to one fibre) contributes equally to the formation of subjective space would find much evidence to substantiate it; for example, the apparent uniformity of the brightness of the visual field, in spite of the variations in population of sense-cells in the retina; variations in subjective velocity of bodies moving at constant velocity in the field of vision, etc.

The gross distortion of subjective space in the region of the blind spot, because of the lack of sense-cells in the optic disk, is well demonstrated by the subjective filling in of various incomplete figures made to fall across the blind spot, as described by Helmholtz and others.

A binocular phenomenon which I have recently observed has some bearing on this and related questions. If a stereoscopic photograph is examined, first so that the relief stands out, and then by inverting so that although the two halves fuse there is no stereoscopic effect, the objects in the picture appear to increase in size. If one eye is then closed, the original sizes return. Reversing the procedure gives opposite effects.

An arrangement of mirrors was set up so that the right eye would see from the point of view of the left eye, and the left eye that of the right, so that binocular fusion without relief would be obtained. Observers were asked to judge the lengths of slips of paper held successively in the field of view, first with one eye only and then with both eyes. Estimates of size in the two cases were in the ratio of 3 to 4; that is, there is an apparent magnification in area of almost two.

It would seem that binocular fusion without stereoscopic effect is equivalent to doubling the numbers of active sense-cells and consequently the subjective size, while where stereoscopic vision is concerned some sort of unification of corresponding sense-cells in the two eyes takes place so that they behave as one—a possible explanation also of Fechner's paradox.

Role of Adenine Nucleotides and Growth Factors in Increased Proliferation following Damage to Cells

STIMULATION to tissue repair in wound healing has been attributed variously to polypeptides and amino-acids[1], sulphhydryl compounds[2], nucleoproteins[3], fatty acids[4], or certain nucleic acid derivatives[5], and it has been proposed that the stimulating substances are secretions of leucocytes ("trephones"[1]) or damaged-cell disintegration products ("wound hormones"[13]). Since cell secretions or damaged-cell products influence normal cells through the intercellular *milieu*, a direct and quantitative approach to this problem is afforded by the comparison of intercellular fluids from damaged cells (I) and from normal cells (II), with regard to their chemical composition and effects on cell metabolism. Such comparisons have shown that (I) greatly exceeds (II) in stimulating cellular proliferation[6,7] and respiration[8,9] and in increasing capillary permeability[10], and that when (I), but not (II), from animal tissue sources is injected repeatedly into animals, overgrowths result[7].

In the following experiments, cell-free, injured-cell suspension fluids (I) and normal-cell suspension fluids (II) from yeast suspensions (*S. cerevisiæ*, F. B. Strain, 100 gm. per l. in distilled water) were compared. Injury was by 8 hr. sublethal ultra-violet irradiation[11], which produced negligible cytolysis, but caused marked increase in the permeability of the damaged cells, accompanied by loss of turgor and shrinkage in cell volume (*ca.* 30 per cent). Both (I) and (II) were substantially free from protein, as in previous experiments[6] (negative biuret and phosphotungstic acid tests and negligible 2700–2800 A. absorption characteristic of proteins, tyrosine or tryptophane). The proliferation-stimulating potencies of (I) and (II) were respectively 98·0 and 3·3 growth units per ml.[12], the solid contents 3·17 and 0·245 mgm. per ml. and the ultra-violet absorption $([1/x]\log_{10}[I_0/I_x])$ at 2600 A., characteristic of nucleotides, 7·0 and 1·4. Thus, the grossly intact damaged cells released, as a result of increased permeability, appreciable amounts of growth-stimulating substances and nucleotides.

EFFECT OF ADENENINE NUCLEOTIDES, KNOWN GROWTH FACTORS, AMINO-ACIDS AND DAMAGED-CELL PRODUCTS ON THE GROWTH OF YEAST IN READER'S MEDIUM.

Addition to medium (concentrations in the cultures)	24 hr. yeast crop, mgm. (wet weight) per ml. (initial seeding, 0·064 mgm. per ml.)		
	R	*R+A*	*R+A+B*
Supplements only (controls) ..	0·152	3·08	4·43
(I) Intercellular fluids from injured cells, 0·05 ml. per ml.	3·70	4·03	5·04
(II) Intercellular fluids from uninjured cells, 0·05 ml. per ml.	0·803	3·00	4·31
Adenosine, 5×10^{-5} molar ..	0·416	3·21	4·50
Muscle adenylic acid, 5×10^{-5} molar	0·488	3·44	4·65
Adenyl pyrophosphate, 5×10^{-5} molar	0·309	3·32	4·85
Same, $2·5 \times 10^{-4}$ molar ..	0·624	3·70	5·52

R = Reader's medium[20].

A = following supplements (γ per ml. of culture): aneurin 0·25, pyrodoxin 0·50, biotin 0·000125, calcium pantothenate 0·125, riboflavin 0·5, choline 0·75, nicotinamide 2·5.

B = following supplements (all 0·625 mgm. per ml. of culture): glutamic acid, asparagine, aspartic acid, leucine, arginine.

The similarity of the spectra of (I) to adenine[14] in (*a*) selective absorption, (*b*) stability to *p*H change, and (*c*) lack of degradation by prolonged ultra-violet irradiation suggested an investigation of the proliferation-promoting effects of various adenine nucleotides. The absorption of (I) was equivalent to an adenine molarity of 5×10^{-4}. In corresponding concentrations, yeast nucleic acid and yeast adenylic acid appeared to be inactive. Adenosine, muscle adenylic acid and adenyl pyrophosphate all stimulated growth, the response with the last being most typical of that with (I) in the growth period up to 24 hours. In all instances, the activities of the nucleotides were much less than that of (I), indicating the presence of other growth factors in (I). Accordingly, the effects of (I), (II), adenosine, muscle adenylic acid and adenyl pyrophosphate were tried in combination with known growth factors and amino acids. The combined supplements, growth factors and amino acids, masked the stimulating effect of (II) but not of (I)[15], as shown in the accompanying table, confirming similar results of Cook[16]. Addition of adenosine, muscle adenylic acid or adenyl pyrophosphate to supplemented media gave increased growth in all instances. The higher concentration of adenyl pyrophosphate plus growth factors duplicated the effect of (I) in growth kinetics and total growth response, and the addition of adenyl pyrophosphate at this concentration to media containing both supplements, growth factors and amino-acids resulted in increased growth somewhat greater than that obtained by addition of (I).

Assays of (I) and (II) for known growth factors[17] showed appreciable quantities of biotin, pantothenic acid, pyridoxine, nicotinic acid and folic acids in (I) but not in (II). Preliminary tests (not regarded as final) for diphospho- and triphosphopyridine nucleotides in (I) were negative[18]. In manometric studies, both adenyl pyrophosphate and (I), but not biotin or yeast adenylic acid, were found to elevate markedly the oxygen uptake and respiratory quotient of growing or resting yeast cells[9], simulating phenomena frequently observed in damaged cells and tissues[19].

Two conclusions appear of particular interest: (1) adenine nucleotides (not hitherto regarded as growth factors) stimulate the growth of yeast in well-supplemented media, and (2) the metabolic effects of suspension fluids from damaged yeast cells are duplicated by combinations of adenine nucleotides and known growth factors. It remains to be determined to what extent the release of known growth factors and nucleotides by injured animal tissue cells plays a part in tissue metabolism and repair following injury.

I wish to thank Dr. Fritz Lippmann, of the Harvard Medical School, for supplying several of the nucleotides and for his kindly interest in the investigations.

Sexuality in *Dugesia tigrina* (syn. *Planaria maculata*)

Individuals of the striped variety of *Dugesia tigrina* collected in the summer of 1935 in the pond behind the Episcopal Church, Falmouth, Mass., have been maintained in the laboratory in finger bowls containing tap water and have been fed beef liver twice or three times a week. During their seven-year stay in the laboratory they have produced egg capsules annually.

In the spring of 1941 the egg capsules deposited by the members of the original 1935 stock were isolated. The worms (F_1) hatching from them were raised under the same conditions as the parents. During the current spring (1942), these animals (F_1) produced cocoons from which viable worms (F_2) emerged.

Hyman[1] presents the theory that individuals of *D. tigrina* living in quiet water remain asexual and those subjected to a strong current or violent waves become sexual, producing many cocoons[1].

Neither the F_1 nor the F_2 planarians have ever been exposed to any strong current, and their parents and grandparents have lived a quiet, sheltered life for six and seven years respectively.

The data are not compatible with the theory that "moving water is the essential environmental factor in the development of sexuality in *D. tigrina*". This hypothesis could only be tenable were we to concede that the F_1 and F_2 animals become sexual because their ancestors at one time were exposed to moving water. This, the present available facts do not justify.

The Public Schools in Great Britain

The recent appointment of a Committee on Public Schools by the President of the Board of Education has stimulated much discussion on the function of the public schools. The main object of this Committee is "to consider means whereby the association between the Public Schools and the general educational system of the country could be developed and extended". The Committee's terms of reference imply only a modification of the existing system. It is for this reason that we issue this statement raising the whole question of the existence of the public schools.

The constitutions of the schools included in the Public Schools Year Book vary considerably. In this document we use the term 'public school' to denote those schools which do not receive grants from the Treasury and which are maintained solely by fees and endowments.

Britain is the only great industrial country where wealth systematically buys a different type of education for its offspring; where education sets a different aim for the wealthy than for those less well off. We thus preserve a system in striking contrast to those of the U.S.A. and U.S.S.R., and of those smaller democracies such as the Scandinavian, to whose social institutions we look with admiration.

The system of public school education is undemocratic. It segregates those children who, by inheritance, proceed to leading positions in industry, politics, the civil services, the armed forces, and by its training strengthens their social privileges. It is socially injurious, since it divorces this section of our people from the rest, from the life of the main part of the community, especially from all those engaged in the productive processes and manual and technical labour. Men brought up in the public school tradition are out of touch with modern social realities and often incapable of grasping modern social problems.

The prospect of endowing these schools with Treasury grants is usually linked with a proposal to admit into these schools a limited number of the more gifted members of the poorer sections of society. This proposal is born as much from the financial crisis of the public schools as from an awareness of their social responsibilities. If it were adopted, the main results would be:

(*a*) a direct subsidy given by the taxpayer to the schools of the wealthy;

(*b*) the psychological dislocation of the gifted poor boys, who would thus be in the position of poor relation in the family of the rich;

(*c*) the stultification of the gifts of these hostages, since in this atmosphere they would lose contact with the life and problems of the mass of the people;

(*d*) the intellectual impoverishment of the State-aided secondary schools which would thus lose their most gifted pupils.

However much the study of the natural and social sciences is cultivated in the public schools, the divorce between this type of education and life cannot be overcome. Science under these social conditions tends to become an esoteric cult, isolated from social purpose. If non-scientific subjects are adapted to social ends, the public schools tend to develop into institutions for the training of 'leaders', that is, into political academies for the firmer establishment of the dominance of a class. The type of social conscience thus engendered, and expressing itself in this sort of reform, is undemocratic and reactionary.

Any botching and patching of the existing public school system will necessarily tend, whether or not by intent, to perpetuate present evils and inequality. It is true that some public schools possess, at present, advantages from a technical-pedagogical point of view over State-aided secondary schools. But this is no reason for prolonging their existence in their present form. Let us see their educational methods, their organization and their personnel applied to the service of a wider community than the wealthy.

We do not ignore the fact that State-aided secondary education stands in need of considerable reform. Much adjustment is needed in the matter of school government, of curricula, of social status. Once the dichotomy in our secondary education is overcome a concerted drive for reforms in these fields can be made, undistracted by considerations of social prestige and privilege.

We call, therefore, for the full incorporation of the public schools into a unified, State-aided system of secondary education as a step towards democracy in our educational system and towards greater health in our national life.

RESEARCH ITEMS

Structure of Salivary Gland Chromosomes

M. KODANI (*J. Hered.*, 33, 115; 1942) has continued his experiments of treating salivary-gland chromosomes with alkalis. By using urea-alkali mixtures he has been able to produce further changes over and above the lamp-brush effect and thereby arrives at certain conclusions regarding the structure of the normal salivary gland chromosome. Three different series of transformations under treatment were produced and these are shown to result from different modes of migration of part of the nucleic acid from a peripheral position to the chromonemata in the centre of the chromosome. The number of chromonemata per chromosome is definitely four; not polytene as stated by others earlier. Two chromonemata are coiled intimately and in each disk expand laterally; the other two chromonemata coil also and form loops in the opposite direction in each disk. There appears to be a membrane to the chromosome, but whether this is an artefact or a reality is not yet determined although the effect of nuclease treatment would suggest the presence of a membrane in the normal chromosome.

Isolation and Collection of Salivary Gland Chromosomes

J. B. Buck and A. M. Melland (*J. Hered.*, 33, 173; 1942) describe various methods for the preparation of salivary gland chromosomes for analysis by X-ray diffraction and electron-diffraction. Dissection of the chromosomes from cells mounted in egg-albumen or water were feasible but the chromosomes underwent further changes in time. Therefore the chromosomes were first fixed in osmium tetroxide, acetic acid, or formalin sufficiently long to make the nuclear membrane brittle enough to be cracked open. The chromosomes were collected by a micro-pipette and transferred to collodion membrane and centrifuged to Pyrex glass capillaries. Preparations of 6,500 nuclei, 1,000 nuclei and 800 nuclei respectively were photographed by X-ray diffraction methods without success. Electron diffraction of mounted chromosomes gave one ring of 3·4 A., which is suggestive. A block of chromosomes orientated in parallel fashion containing 1,253 chromosomes and measuring 0·25 × 0·25 × 0·05 mm. were photographed by Dr. W. T. Astbury. X-ray diffraction results again gave suggestive effects. The technique, when developed, will be useful in future work.

Lower Devonian Plants

NEW and rich fossil localities discovered in the Senni Beds of Monmouthshire and Breconshire have yielded the most extensive and representative flora of late Lower Old Red Sandstone age in Britain (W. N. Croft and W. H. Lang, *Phil. Trans. Roy. Soc.*, B, 131, ; June, 1942). The specimens are represented by thin incrustations or by impressions, hence the information afforded is mostly relative to external morphology. The remains of a spiny plant of *Psilophyton princeps* type have a hitherto undescribed fructification in organic connexion with the vegetative shoots. This fructification is quite unlike Dawsonites of which typical examples also occur. Numerous specimens of Gosslingia have shown that the sporangia were not borne on special fertile branches as was originally supposed but on the margins of the regular dorsiventral branch system. Zosterophyllum is divided into two subgenera, one with radial spikes and a new species with dorsiventral second spikes of sporangia. Good examples of Cooksonia continue this type from the Downtonian to the Senni Beds, while Sporogonites, Sciadophyton and Taeniocrada are recorded for the first time from British rocks. Prototaxites and Nematothallus occur along with the vascular plants, and Pachytheca is represented in several exposures.

New Species of Fungi

SEVERAL descriptions of new species of fungi have recently appeared (*Trans. Brit. Mycol. Soc.*, 25, Pt. 3; June, 1942). T. Petch, in his continued studies on entomogenous fungi, finds new taxonomic units in *Calonectria truncata*, from leaf hoppers in the West Indies, *Hymenostilbe aphidis*, also from the West Indies, *Isaria* (*Beauveria*) *sphærocephala* from lepidopterous larvæ in Ceylon, and *Cephalosporium subclavatum* from similar larvæ in Great Britain. Elizabeth G. Gray has described *Phialea mucosa* as a new species. It appears to be the cause of blind spot disease of rye-grass, a malady originally studied by Neill and Hyde in 1939.

Gravity Measurements in Guatemala

AT the suggestion of E. G. Zies of the geophysical laboratory of the Carnegie Institution of Washington who is working on the volcanoes Santa Maria and Santiaguito, F. E. Wright has made gravity measurements in the neighbourhood of the volcanoes ("Gravity Measurements in Guatemala", by F. E. Wright. Geophysical Laboratory, Carnegie Institution of Washington, 1941, No. 1049). It was suggested that if a network of accurate gravity stations were to be established in the Santa Maria volcano region and the measurements were repeated at these stations periodically, changes in the values of gravity at the stations might serve to indicate the migration of the molten rock below the volcano towards the surface. In establishing each gravity station of the series its exact elevation was determined in order that, if a change in the observed value of gravity were obtained at a given station, it would be possible to ascertain if the change were due to uplift or downwarp of the surface at that point or to a shift in underlying rock masses and the upward movement of the molten mass. Magnetic and other measurements were made for comparison with the gravity measurements. The gravity measurements were made with a Brown gravity pendulum loaned by the United States Coast and Geodetic Survey and a base station was occupied at Washington. Numerous difficulties were encountered, notably in connexion with the radio time signals on account of interference, and the flexure of the basement floor of the observatory, but the following results were obtained, previous results being given for comparison:

Station	Observer	Year	Gravity gals.	Elevation metres
Guatemala City	Pedro Sanchez	1935	977·973	1,494
	Shell Company	1938	977·986	1,494
	F. E. Wright	1940	977·985	1,494
Quezaltenango	F. E. Wright	1940	977·781	2,384

Drifting Force on a Ship among Waves

WHEN a ship is advancing through a train of waves it experiences an average steady resistance greater than that at the same speed in smooth water. Study of the wave pressure due to the reflexion or scattering of the ocean waves of the surface of the ship involves second-order terms in the hydrodynamical equations. A solution is difficult but approximate calculations appear to show that the effect would account for a small fraction only of the total effect. T. E. Havelock continues his researches upon the subject by making tentative calculations associating the effect directly with the oscillations of the ship (*Phil. Mag.*, 33, 467; 1942). A steady average drifting force is obtained depending upon the phase differences between the heaving and pitching motions and the periodic forces and couples due to the wave motion. Although the available experimental data are not suitable for detailed comparison, the calculations give drifting forces of the same order of magnitude.

Stress Distributions in Solids of Revolution

THE theoretical determination of stress distributions in such complete solids of revolution as twisted shafts of non-uniform diameter, axially symmetrical pressure vessels and in incomplete tores such as helical springs of small pitch, beams of large curvature or hooks is extremely difficult by orthodox methods on account of the boundary conditions. Recent extensions of the relaxation method have gone far to remove the difficulties, and lately trial has shown them to be surmountable. Consequently, the analysis has now acquired utility and has been given by R. V. Southwell (*Proc. Roy. Soc.*, A, **180**, 367; 1942) as a background to papers in course of preparation. The 'semi-indirect' method of Saint Venant is applied to determine directly, that is, without explicit reference to strains, the stress distributions in these solids. As the paper is intended as a prelude to approximate but general treatment of relaxation methods, only simple examples are given, but a comparison is made with earlier solutions less suited to a 'relaxation' approach.

Thermal Vibrations and Scattering of X-Rays

M. BORN continues his studies of the subject in a third paper (*Proc. Roy. Soc.*, A, **140**, 397; 1942). C. V. Raman's explanation of the diffuse scattering is compared with the 'thermal' theory which in its revised forms satisfies the demand of a theory based on quantum principles. The relationships of the dynamical matrix, describing the mechanical properties of the lattice and the scattering matrix, describing the scattering power are discussed, together with the influence of the ordinary Raman effect on the scattering.

Spectrographic Observations at the Total Eclipse of October 1, 1940

R. O. REDMAN has prepared two papers on this subject (*Mon. Not. Roy. Astro. Soc.*, 102, 3; 1942), the first of which, "Instrument and Observational Procedure", is summarized in the present note. The second paper is only the first of a series dealing with spectrographic observations. The author was with the eclipse party at Calvinia. It is interesting to notice that a correction was made to the tabular longitude of the moon of 0·8″ instead of the *Nautical Almanac* value 2″ and, in spite of this better value, totality came more than 3 seconds earlier than the predicted time. A number of suggestions and also some criticisms are offered for the advantage of those who may make observations with similar, though improved apparatus, at eclipses in the future. Among these may be noted the suggestion that the cœlostat drive should be rated to follow the moon. The cœlostat and concave mirror mountings should be mounted substantially; it was found that the mount for the concave mirror at Cavinia vibrated even in a gentle breeze, and it was necessary to load it heavily with bricks. A mechanical drive rather than the hand drive is recommended for the camera; however skilful and careful the operator may be, a hand drive cannot give the regularity of a machine. Instead of starting exposures by using the computed time, it seems possible that better results would be obtained by estimating the time from the size of the disappearing crescent just before second contact. The success of the pit made for the instruments requiring thermal protection suggests this method for future eclipses, provided local conditions are suitable.

Recent Changes in the Spectrum of γ Cassiopeiæ

MISS E. M. PEACHEY has described the changes in the spectra of γ Cassiopeiæ obtained on thirty-five plates taken at the University of London Observatory between July 8 and November 22, 1940 (*Mon. Not. Roy. Astro. Soc.*, 102, 3, 1942). During this period, the hydrogen lines of the Balmer series varied from very sharp, strong absorptions with faint emission borders to broad, fainter, diffuse absorption lines. Similar variations were observed, but to a much smaller extent, with the lines of Helium I. A plate shows eighteen spectra which have been selected as typical and it includes two additional spectra taken during the summer of 1939. The latter show the transition from the emission-line stage to the sharp absorption stage. A certain amount of detail which was visible on the original negative has been lost in reproducing the plate, but the changes described in the paper are easily seen. One particular feature shown on the plate is the general broadening of the lines and their subsequent narrowing on November 19 and 20 before they returned to normal on November 22. A summary of the observed changes in the spectrum is given and it is suggested that more plates, obtained with an instrument of higher dispersion, should be taken when rapid changes in the star are noticed.

Sunspots during 1938

A PAPER on the mean areas and heliographic latitudes of sunspots during 1938 has been communicated by the Astronomer Royal to *Mon. Not. Roy. Astro. Soc.*, 102, 3, 1942, and is a continuation of earlier results. (*Mon. Not.*, 100, 495, 1940). The measurements of photographs taken at the Royal Observatories of Greenwich and the Cape and at the Kodaikanal Observatory, India, were conducted at Greenwich, and the results are given in four tables. The years 1937–38 constitute a notable sunspot maximum compared with the outstanding peak of 1870 (Kew photographs) and those of 1837, 1788 and 1778 (Wolf's numbers). In 1938 the southern hemisphere showed greater activity in contrast with 1937, when the northern hemisphere was more active. During 1938 there were thirty spots which were not less than 500 millionths of the sun's hemisphere in mean area, and of these, nine were of mean area greater than 1,000 millionths. One of these great groups had a mean area of 2,955 millionths and was the second largest group ever recorded at Greenwich. The latitudes for individual spots ranged from 0·7° to 45·6°, and the mean latitude of all spots weighted according to area was 14·8°. The mean latitude thus continues the equatorward progression of the mean spot belt in the two hemispheres during the eleven-year cycle. The above figures are based upon two one-day spots, but the range was found to be from 1·8° to 42·1° for spots of duration not less than two days.

THE LEAGUE OF NATIONS

A REPORT on the work of the League of Nations, 1941–42, which has been submitted by the Acting Secretary-General, well indicates the valuable contribution which the League should be able to make to the solution of problems of reconstruction, European relief, and the like, apart altogether from whatever value its organization and machinery may possess as a starting point for a fresh attempt to organize peace and to plan international co-operation.

Dealing first with economic, financial and transit questions, the report notes that the League's World Economic Survey, its Statistical Year-book and the *Monthly Bulletin of Statistics* have been maintained, and while the headquarters at Geneva have specialized on European developments, the part of the Economic, Financial and Transit Department sent on mission to Princeton follows the course of events in the rest of the world. In addition to the three pivotal publications already mentioned, the Secretary-General proposes to publish this year the statistical part of the work previously published in two volumes under the title "Money and Banking".

In regard to post-war economic problems, the programme visualized for 1942 is guided by three principles. Since the future must be built on the past, it is essential before planning and projecting that building to ascertain the causes of success or failure in the recent past, and to learn and apply the lessons which may be deduced from the past. Secondly, such evidence must be supported by an adequate basis of fact, the relevant information being collated and analysed to assist those responsible for the formulation of policy to frame their own judgment on them. Thirdly, the care of the social and economic issues of the future is likely to be the problem of social security, and the means by which control of the two groups of dynamic forces at present discernible in modern society may be rendered effective should therefore constitute the central thread of all constructive thinking for the future, and all future policies must be considered in the light of their probable effect on economic stability, on demographic conditions, and on social security. The programme includes commercial studies, one of which, "Europe's Trade", has already been published, studies on raw materials such as obstructions to free access, control schemes, raw-material shortages and surpluses at the end of the War of 1914–18 and on proposals to secure equal conditions of supply or prevent violent fluctuations in price, as well as on the whole experience of relief and reconstruction. In regard to agriculture, a careful study is being made of current agricultural developments in war areas and elsewhere. International currency problems, economic depressions and social security and demographic questions are also receiving attention, as well as transport in relation to post-war relief and reconstruction and the preparatory examination of the future international organization of transport. A full programme of studies on European demographic problems is outlined in the report.

In regard to social and humanitarian questions, the Secretary-General's report describes the way in which the Health Section continues to deal with questions of epidemic disease. The service of Epidemiological Intelligence and Public Health Statistics has continued, with interruptions, and Singapore Bureau has now been re-opened in Australia, where it is carrying on within the limits imposed by war conditions. The *Weekly Epidemiological Record* has appeared regularly at Geneva without any interruption and an annual Epidemiological Report was distributed at the end of 1941. The standardization of sera and of vitamins has continued, and results of the latest research conducted under the Commission were published in 1941 in the *Bulletin of the Health Organisation*. The Health Section is also endeavouring to ascertain the effect of food rationing on the general level of health of European populations, and has supplied information on numerous health questions such as the effect of the War on the health situation, typhus, tuberculosis, feeding and nutrition, etc.; reference is made to the future opportunities for action which the field of nutrition appears to offer the Health Organisation.

Activities in regard to the control of the drug traffic have been essentially maintained, and the Permanent Control Opium Board continues to watch the international trade in narcotic drugs on the basis of statistical information supplied by Governments. The Child Welfare Information Centre has been maintained and intellectual co-operation has continued in the United States, where the national committees of that continent held their second conference at Havana in November 1941. The programme included the examination of the basic principles upon which intellectual co-operation depends: improvement of copyright regulations; removal of obstacles to cultural and intellectual exchange, such as high duties on books, excessive postal rates. International assistance to refugees is being continued on the lines laid down by the Assembly in September 1938, and brief reference is made to such matters as mandates, slavery, the protection of minorities and the registration of treaties where the League's administrative work has been interrupted or restricted by the War.

The report includes an analysis of the League's budget and of the reduction in the staff of the secretariat, but gives an encouraging and indeed surprising picture of the maintenance of economic, social and humanitarian activity and of the conservation of reserves in readiness for the resumption of co-operation and the handling of reconstruction problems.

MAN-POWER IN THE NATIONAL FIRE SERVICE

IT seems clear, from the thirteenth report of the Select Committee on National Expenditure, dealing with the National Fire Service, that the administration of the Service is already under close scrutiny from within, and that active steps are already being taken to discover ways and means of simplifying the administration and reducing the staff. Centralization of the administration at area headquarters requires speeding up in urban areas, while in rural areas decentralization is the recommended policy, with a more direct connexion between region and division. Amalgamation of some of the administrative posts, such as establishments and stores, appears to be possible, and experience in Scotland should provide a useful guide as to some of the possibilities in this direction.

The question of man-power is one of the major problems considered by the report. Partly it is approached from the point of view of utilizing in some effective way the time of the men who are standing by, and the report recommends that the fullest use should be made of the skilled men in the Service by the setting up of workshops for the repair of motor-vehicles and also for the repair of uniforms.

While the report recommends that the practice of allowing men on duty to do some industrial work at their stations should be encouraged and expanded at once to the utmost extent possible without interfering with their routine duties and training, the attitude of the Select Committee on this question is similar to that of Mr. Morrison as indicated in his speech on July 30; neither seems to realize the very serious problem of man-power which is involved and is likely to increase in gravity. The Committee's objection to the 24–24 hour system that such a practice may not be good for the Service, as a man may very easily become more interested in his civilian job, can scarcely be taken seriously in the present situation. If a uniform system of hours is to be adopted for the whole country, as the Committee recommends, the effects of the 24–24 hours system with the men directed to eight-hour factory shifts on their days off during lulls, as is being attempted in the north-west of England, should be examined.

Somewhat surprisingly, the other aspect of this question of hours and of the importance of alternative occupation is rather overlooked by the Committee. The report shows little appreciation of the real dangers to efficiency which arise from keeping men too long confined to their stations, and insufficient attention is given to welfare work in the National Fire Service. The Committee in fact scarcely appears to realize that the troubles of the National Fire Service spring chiefly from long periods of inaction and the failure to divert or occupy its members; indeed it suggests that welfare should be primarily the responsibility of the various commanding officers, assisted by the establishment officer, and it is recommended that welfare officers should not be specially appointed. Probably officers who can find leisure occupation for the men and watch over their conditions of living, eating and sleeping are the greatest need of the National Fire Service to-day. Moreover, although a wide view of welfare not limited to sporting activities is taken, nothing is said on the question of educational service. That has still to receive official encouragement; indeed in London, where it was commenced by the men, it was for long hindered rather than helped, and other regions have nothing of the kind. Nevertheless, the need of the Fire Service for educational service is just as great as that of the Army, where its value has long been recognized.

There are few ways in which the local authorities could better display their interest in the fire service now that it has been nationalized. The health and cultural welfare of this body of men, their own citizens, though now serving in a national force, gives a great opportunity. They could do much to support educational schemes, even if they cannot assist in their initiation, and to demand and maintain good living conditions. Whatever advantages there may have been in a local service with its fuller knowledge of local conditions could at least be utilized in welfare work, with benefit in efficiency and morale.

To bring to concert pitch, adequately but not overstaffed, such a force as the National Fire Service, and to maintain that efficiency over prolonged periods of inactivity, demand inspired leadership alive to the human issues as well as to the technical problems involved.

CONTACT RESISTANCE

THE effects of contact resistance on temperature rise in switches are examined by R. W. J. Cockram in the *Electrical Review* of August 21. A factor complicating the control of electric circuits is the contact resistance set up between two mating surfaces of metal which at times have to be separated in order to break continuity of supply. The two main methods of decreasing contact resistance—excluding the use of special contact tips—are to increase the contact area and to increase the contact pressure. Contact pressure can be increased only to a certain limit, beyond which it results in a welding-in of contacts. Large contact surfaces are uneconomical; they are, in fact, made as small as possible consistent with a contact pressure low enough to preclude welding-in.

Knife type contacts depend mainly on large contact-surface area rather than high mating surface pressures to maintain low resistance values. Unless enclosed they are operated only under no-load conditions, and should not be worked in excess of 500 amp./sq. in. Point butt-type contacts mainly find application on instrument-control switches, control-circuit contacts or interlocks on contactor gear. Rarely rated above 5 amp. at 440 volts, their contacts are usually of silver and take the form of portions of spheres, two breaks in series being employed. A slight 'wiping' action takes place which assists oxide removal. Line butt-type contacts are also chiefly associated with contactor apparatus. In these, heavy pressures are applied, generally to the main poles of contactors up to 150 amp. with spring pressures of 8–10 lb./sq. in. Replaceable contact tips are used, and a degree of wiping is provided. Surface type contacts call for complete mating of the contact surfaces; each moving contact is divided into four segments, each segment being acted upon by two springs. Taper-butt surfaces are employed for the control of heavy currents, as in circuit breakers and similar equipment.

In all the forms of contacts cited, pressure is applied to the mating surfaces. Some small degree of spot welding may be permitted while the wiping action is sufficient to break it; it is, however, best prevented. Burning and pitting was at one time considered to take place during the breaking of circuits but it is now mainly attributed to imperfect mating over long periods in the engaged position, the resulting oxidation causing further heating. Silver contacts are accordingly used, giving a greater working life since silver oxide is a comparatively good conductor.

MAGNETIC FLUXMETER

MEASUREMENT of magnetic field strength due to current in a coil is usually made by changing the current and observing the voltage induced in a search coil or in the coil itself. This voltage is proportional to the rate at which the magnetic flux varies and it fluctuates in magnitude and direction, if the field pulsates or alternates. For rapid flux alternations a galvanometer will show no deflexion, but a steady reading can be obtained if the galvanometer connexions are reversed as the induced current reverses. The deflexion is then a measure of the magnetic field under observation. A practical application of this method is the measurement of voltage induced in a relay by the operation of a neighbouring relay.

A fluxmeter working on these principles has been developed in the Bell Laboratories and is described by E. L. Norton (*Bell Lab. Rec.*, 20, No. 10; June, 1942). It has a pulse generating device operating high-speed relays which reverse simultaneously the current producing the flux and the meter connexions. Pulse rates of 30, 15, 7·5 and 3·75 per sec. are obtained from gas tube discharges as submultiples of 60-cycle alternating current. The measuring circuit includes a bridge which is used when flux is measured by the voltage induced in the coil itself. Switching is so arranged that, when not pulsing, the bridge may be balanced using the indicating meter as a galvanometer. A loss pad is incorporated enabling the meter to read one third- or one tenth of the actual current. This apparatus gives readings more conveniently and accurately than previous magnetic fluxmeter readings usually made with a ballistic galvanometer. In addition, it has the added advantage of being suitable for adaption to a portable construction.

FORTHCOMING EVENTS

Tuesday, September 22

INSTITUTE OF PHYSICS (at the Royal Institution, Albemarle Street, London, W.1), at 11 a.m.—Discussion on "The Determination of Equilibrium Diagrams by X-Ray Methods". (Opening speakers: Dr. A. J. Bradley, F.R.S., Dr. W. Hume-Rothery, F.R.S., Dr. M. L. V. Gayler, Prof. E. A. Owen.)

Wednesday, September 23

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 2.15 p.m.—Presidential Address. Mr. H. Rottenburg: "Publishers and the Universal Decimal Classification".

Saturday, September 26

SOCIETY OF CHEMICAL INDUSTRY (JOINT MEETING OF THE MANCHESTER SECTION AND THE FOOD GROUP) (in the Reynolds Hall, College of Technology, Manchester), at 2.30 p.m.—Dr. L. H. Lampitt: "The Preservation of Foodstuffs".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DRAINAGE ENGINEER to the Hampshire Rivers Catchment Board—The Clerk to the Board, The Castle, Winchester (September 28).

DIRECTOR OF THE CHEMICAL RESEARCH LABORATORY, TEDDINGTON—The Secretary, Central Register (Ref. F690), Ministry of Labour and National Service, Sardinia Street, Kingsway. London, W.C.2 (September 30).

TEACHER OF ELECTRICAL ENGINEERING—The Principal, Wolverton Technical College, Wolverton, Bucks. (October 3).

LECTURER IN PHYSIOLOGY—The Principal, Liverpool Physical Training College, Barkhill Road, Liverpool 17.

GRADUATE LECTURER with good Honours or higher qualifications in MATHEMATICS—The Principal, Neath Mining and Technical Institute, Neath, Glamorgan.

PROBLEMS OF PERSONNEL IN PUBLIC SERVICES

THE problem of personnel in the Civil Service and other public services cannot be considered altogether apart from the nature and range of the work which the post-war public services will be called upon to do, and this in turn is affected by the nature of the social and economic structure of the country. It is not only that free migration and interchange both between the national and municipal services and between these and the public or semi-public corporations is much to be desired, but rather that the essential social structure of the community and the relative importance of the service and the profit motives have important repercussions. It must obviously influence the underlying philosophy of the Civil Servant, whether the source of his inspiration be integrity and tendency to play for safety as in the past, or that more difficult part now needed of reconciling integrity and firmness of administration with the acceptance of responsibility and the capacity for co-ordinated initiative; the character of the new machinery of government is also of fundamental importance. However far that passion for excellence insisted upon by Lord Haldane may sway a reconstructed Civil Service from top to bottom, it will not function with the desired efficiency unless the machinery of government itself is adapted to the new demands. Without any disparagement of a Service which has deservedly earned itself a unique reputation throughout the world, it is clear that adjustment, both of the personnel and of methods of working, is required to meet present and future problems.

Consciousness of this lies behind the views which have openly been expressed in the Press regarding Treasury control and the 'head' of the Civil Service, arising out of the appointment of a new Permanent Secretary of the Treasury. The real point at issue is that of the establishment control stressed in the Haldane report, later in that of the Tomlin Commission and still more recently in a P E P broadsheet. The headship of the Civil Service is an office of great and increasing importance, but it can no longer be usefully combined with the office of Permanent Secretary to the Treasury. The interest in war-time of getting a job done quickly and efficiently, the question of cost being subordinate, is at last compelling recognition in the Civil Service of the principles of staff management as it is understood and practised in modern industry.

Establishment problems are inherent in every form of complex industry and are the regular currency of industrial and business management. Moreover, though it would be rash to assume that all the solutions found successful in the competitive world are applicable to the organization of the Civil Service of Great Britain, the fact that no large concern has found the successful management of its establishment compatible with a close union of staffing and financial functions cannot be disregarded. Cost and economy are considerations fundamentally distinct from those of efficient staff control, the object of which is to see that the right men are found for each job, and then that the conditions of their work are such as to offer the least hindrance to their doing the best that is in them. This is the main test of efficient selection, training, remuneration, promotion, welfare, retirement, or replacement problems, and in these allied questions of the development of efficient methods of working which constitute the essential staffing problems.

The attention which has been directed to such matters in that highly suggestive American report of the President's Committee on Administrative Management should be given careful consideration. Although much of the report is concerned with those problems of the machinery of government which are peculiar to the American constitution, there are sections of profound interest at the present time when the British machinery of government is under examination, and especially in connexion with the nature and extent to which Government control may have to be extended after the War and the manner in which such control should be exercised. Notably is this true of the comments of the report on staff matters and those fundamental principles of administration which are germane to any modern efficient organization.

One of the most important recommendations of this authoritative committee is the development of functional investigation and research into administration problems as a regular aid to management. "Economy and efficiency in government", says the report, "require constant investigation and reorganization of the administrative structure. It is a mistake to assume that government can be reorganized once and for all. A continuous study of the administrative organization of the huge Federal machine is necessary. New activities are constantly emerging and old activities are constantly changing, increasing or disappearing. Unless there is a special agency equipped to investigate problems of organization, new activities are set up without careful attention as to where they should be located and what kind of organization is required. On the other hand, when the need for certain government activities declines or disappears, unless there is a special agency constantly studying the organizational requirements, adjustments are made late or not at all."

The application of this argument to British conditions needs no further emphasis, and the fate of the Haldane report, to which this President's Committee's report is the American counterpart, though on a larger scale, is sufficient warning of the danger of continued neglect. In addition to the establishment of a Civil Service Administrator and a Civil Service Board to handle matters of recruitment and management of personnel, the report urges that a division of administrative research in the Bureau of the Budget is the logical place to develop these functions, and it is clear from the outline of the functions of the Division given in the report that the President's Committee has very clear ideas as to the Division's independence and freedom from defects which characterize Treasury control in Great Britain.

"The Division", says the report, "should stimulate the continuous study of organization, methods of procedure, at the departmental or bureau level by the Departments and Bureaux themselves. It should engage in such studies on its own initiative where necessary but should follow the policy of aiding and encouraging the Departments in the study of their own organization procedural problems. It should endeavour to develop principles of organization that have general applicability and to act as a clearing house, consultation centre for administrative research regarding the Department. Persons engaged in administrative research should be free from routine duties involving handling budget estimates. The administrative research activity should be concentrated in a separate division of the Bureau of the Budget. It should be headed by a permanent chief possessing in unusual degree imagination, vision, creativeness and analytical insight as well as intimate acquaintanceship with both the practices of government and the principles of public administration. The research division must be staffed with persons of unusually high competence. Important research assignments upon administrative problems can be carried out successfully only by highly trained and experienced persons familiar with the organization techniques of public administration."

The sanity and breadth of vision of this admirable report should earn for it widespread attention in Great Britain. Government, in its view, is a 'going concern', not a static institution. New activities should be organized on the basis of purpose, so that purpose may be the central driving force of the organization. While, however, new purposes cannot be achieved without broad freedom to experiment, when an activity is organized, its major policies established, its purposes accepted and understood, and its work in the main placed on a routine basis, the activity should be brought into the normal structure of organization and under the normal conditions.

The bearing of these observations on government problems in regard to reconstruction agencies is quite clear ; those on the human aspects of government and the note that reorganization should be approached as a problem of morale and personnel fully as much as a task of logic and management are equally important. Nor are they irrelevant to the organization of the war effort. Honesty and courage alone are not enough for victory, either in peace or in war. Intelligence, vision, fairness, firmness and flexibility are required in an assembled competent strong organization of democracy. Strong executive leadership is essential to democratic government to-day—on that point there is complete unanimity among critics of H. M. Government both in the field of strategy and in that of production, and the American report urges that the forward march of American democracy at this point of its history depends more upon effective management of all its multitudinous activities than upon any other single factor.

From that opinion there will be no dissent. It is equally true in Great Britain, even when we remember that management is a servant, not a master, a means, not an end, a tool in the hands—and for the purposes—of the people. There can be no doubt that, as the two democracies continue to get "mixed up" in their affairs, in Mr. Churchill's phrase, their outlook and motives must interact powerfully on one another. The report of the Committee on Administrative Management will not pass unnoticed in Great Britain.

In a recent House of Lords debate Lord Portal endorsed Lord Reith's remarks about the importance of efficiency in the Civil Service. His statement was largely an outline of the procedure being adopted by the Ministries concerned with post-war reconstruction, but he agreed as to the importance of right timing in handling these matters, and that the necessary schemes for public services should be ready to put into operation at the appropriate time.

Without going into the details of the arrangements outlined by Lord Portal, it is clear that the Government is not unmindful of the importance of the machinery of government and the efficiency of administration. Nothing must be allowed to interfere, for example, with the handling of the transport question so that the greatest transport resources are brought to bear and used most efficiently during the War, but while any effective solution to transport problems is bound, as Lord Portal pointed out, to be controversial, the Ministry of War Transport is preparing its own scheme of reconstruction. Similarly, the Paymaster-General is examining the reorganization of electricity from the point of view of introducing a better diversity of load, greater standardization of voltage and uniformity of charges, adoption of a common policy with regard to development, and placing the best engineering advice at the disposal of all distributors. Water, which comes under the Ministry of Health, gas under the new Ministry of Fuel, Light and Power, and the location of industry under the Board of Trade, are other matters on which reports are at present being collated and submitted to a ministerial committee over which the Paymaster-General presides.

Lord Portal's statement will almost certainly reinforce the plea for wider powers for the new Ministry of Planning. The functions of the Ministry of Works and Buildings are only a section of those which require central co-ordination and direction, and though there are encouraging signs in Lord Portal's statement, the trend of the debates on war production and other matters in which the organization of government is of prime importance does not indicate that the Government in Great Britain has yet taken to heart the arguments so cogently advanced in the United States. It is to be hoped that the increasing contact with the United States and the constructive criticism of the Select Committee on National Expenditure and other bodies may not fail to have their due effect, and will lead to the adoption of the most effective tools and machinery to implement the national effort, no matter what departmental interests or traditional views may bar the way.

RELATIVITY ON PARADE

Introduction to the Theory of Relativity

By Prof. Peter Gabriel Bergmann. (Prentice-Hall Physics Series.) Pp. xvi+287. (New York: Prentice-Hall, Inc., 1942.) 4.50 dollars.

THE number of systematic treatises on relativity is not unduly large. This is partly because, since the first few years after Einstein's announcement of the 'general' theory in 1917, it has undergone no fundamental development, and partly because the early expositions were so good. One cannot forbear mentioning those of Eddington, von Laue, Pauli, and Weyl. But these were addressed mainly to professionals, and, in spite of subsequent accounts from various points of view, there is still room for a plain text-book suitable for undergraduates reading relativity as a special subject, or for research students needing a working knowledge of it. Prof. Bergmann's book is designed to meet such requirements.

The book is in three parts. The first constitutes a fairly comprehensive account of 'special' relativity; it includes an introduction to tensor calculus, and the theory itself is presented in tensor form. The second is a concise account of 'general' relativity; it consists mainly of a general study of the field equations and an account of standard rigorous solutions in special cases, together with a brief account of the experimental tests of the theory, and a sketch of recent work by Einstein, Infeld and Hoffmann showing how the field equations determine the equations of motion. The third is an introduction to 'unified' field theories, that is, those which incorporate also electromagnetic phenomena in a geometrical system as general relativity incorporates gravitational phenomena in its geometry; after an outline of Weyl's gauge-invariant geometry, it provides a formulation of five-dimensional theory which can be applied to projective field-theories, to Kaluza's theory, and to extensions of the latter in which the author has been a recent collaborator with Einstein.

As is to be expected of a book commended in a foreword by Prof. Einstein, it has many admirable and exceedingly valuable features. But it is relativity on parade, a well-ordered march-past of selected units beautifully turned out in parade dress. It is *not* relativity in action, perhaps much less tidy, but full of verve in its adventurous penetration of new territories. Of course, from the parade-ground behaviour of a force, an experienced commander can infer how it will go into action. But to the uninitiated this is not so easy; and one believes that something analogous will represent the experience of different classes of readers of this book.

The author says that "the main emphasis of the book is on the development of the basic ideas of the theory of relativity". Bearing out the foregoing criticism, one actually finds the emphasis falling unduly upon their formal development. Indeed, one wishes that some of the formalism of the development had been spared for the statement of the ideas themselves. Some of these, such as the reason for the linearity of the Lorentz transformation, the principle of general covariance, and the reasons for taking the world-lines of free particles to be ordinary geodesics and those of light-pulses to be null geodesics, are introduced rather casually and obscurely, and their implications by no means clearly brought out. In fact, the whole treatment of the postulates is neither compelling nor profound. For example, a good deal is made of the fact that general relativity overcomes the difficulty of 'action at a distance' by providing a 'field theory' of gravitation. Surely a more comprehensible, while deeper, view is that we are anyhow looking only for a mathematical description of phenomena, and that general relativity provides a better one than classical theory by simply abolishing the dualism between space-time and matter.

There are two remarkable omissions: the cosmological applications of the theory and the fundamental problem of extracting 'observable relations' from the mathematical formalism. These topics have been largely responsible for the resuscitated interest in relativity in recent years and it is surprising to find them not even mentioned as part of "the development of the basic ideas" of the theory. Actually they have been treated at length elsewhere, for example, in a fairly recent book by Tolman, but that suggests another shortcoming of the present book: it contains references for the work that is described, but none for what is omitted from its limited scope.

There are some misprints, slips, and obscurities in the algebra, but those detected by the reviewer are not vital.

The book will prove a valuable adjunct to the teaching of relativity, but, in the reviewer's opinion, it could scarcely be relied upon by itself to give a student a well-balanced grasp of the subject.

W. H. McCrea.

IMMUNITY AGAINST ANIMAL PARASITES

Immunity against Animal Parasites

By Prof. James T. Culbertson. Pp. x+274. (New York: Columbia University Press; London: Oxford University Press, 1941.) 36*s*. 6*d*. net.

This most readable and interesting book is divided into three parts. The first discusses the general principles underlying natural resistance and acquired immunity to parasitic infections. The factors influencing natural resistance to parasitic infection are numerous and no one of them applies to all examples. The importance of the genetic constitution of the host is clearly shown in the differing racial resistance to malaria; negroes—even the very young before natural infection can confuse the issue—sometimes resist all efforts to infect them with *P. vivax*, whereas white persons are uniformly susceptible. Age also plays its part in resistance, and a complete chapter is devoted to the discussion of the various ways in which age influences immunity to parasites. Sex appears relatively unimportant although resistance to a few diseases is apparently influenced by this factor. Intercurrent infections usually result in depression of resistance but in some instances resistance to one parasite may be increased by simultaneous infection by another, as is demonstrated by the diminished pathogenicity of certain trypanosomes in mice infected with spirochætes compared to the same trypanosomal infection alone, and by the behaviour of different species of malarial parasites simultaneously infecting man. The character of the diet also influences profoundly certain parasitic infections; and although the most conspicuous effects are seen upon parasites residing in the alimentary canal, yet there is evidence of dietary influences on some somatic infections. The various organs and tissues also play their own special part in resistance to parasitic infection; the action of the reticulo-endothelial system is well recognized, but the effect of special defensive factors associated with other cells of the host and the influence of various invasive factors of the parasites themselves are not so commonly taken into account.

Turning to acquired immunity, the reader will find that therapeutic application has not perhaps made the progress that might have been hoped. This may well be because of the inherent complexity of the antigenic factors concerned, while an obvious teleological explanation is that the parasites so largely depend upon a tolerant balance between themselves and host. Nevertheless, a considerable amount of knowledge on the principles and mechanism of acquired immunity to parasites has accumulated since the first clear demonstration of such immunity almost fifty years ago, when Theobald Smith and Kilbourne showed that recovery from one attack of Texas fever protected cattle against subsequent attacks, and many aspects of parasitic immunity have been investigated, some with notable success. Premunition, local immunity and the influence of various mechanisms including skin response, agglutination and precipitin reactions, and the adhesion phenomenon are all discussed.

In the second section the various parasites are discussed separately and the specific immunological reactions associated with infection by them are described in detail. This section concludes with an interesting chapter on responses to arthropods, not only to bites and stings but also to somatic infection with such of them as infect the tissues.

The third part, which although short is not the least valuable, is devoted to applied immunology, and besides dealing with the practical diagnosis of parasitic infection by immunological means and the attempts that have been made to protect against such infection, gives an interesting chapter on the classification of parasites on immunological grounds.

It is clear that the chief developments have been in the field of the diagnostic tests for the various parasitic infections of man and domesticated animals, and in some diseases, particularly the somatic helminthiases, eminent success has been attained. These tests employ chiefly the detection of antibody in the tissues or blood, and so far comparatively little practical use has been made of tests for antigen, a matter for some regret, since such tests would have the advantage of detecting infection in its earlier stages. Somewhat disappointing practical results have attended attempts to produce successful vaccines against parasitic infections and it appears extraordinarily difficult to reduce the virulence of an animal parasite while at the same time preserving its natural antigenic qualities. Nevertheless, as complete information becomes available, it appears more and more probable that no fundamental differences exist in the character of the immune responses to the parasites and to other agencies of disease.

Prof. Culbertson, as he himself states, has taken Taliaferro's classical monograph as his point of departure and he has worthily upheld the high tradition of the American school in this field of study. Not only has he most adequately sifted and summarized modern work, but also his text is most clearly annotated with references to original papers, and the book is therefore a very valuable review which should be in the hands of all interested in the subject.

F. Murgatroyd.

A STUDY OF DELINQUENCY

The Adolescent Criminal

A Medico-Sociological Study of 4,000 Male Adolescents. By Dr. W. Norwood East, in collaboration with Dr. Percy Stocks and H. T. P. Young. Pp. xi+327. (London: J. and A. Churchill, Ltd., 1942.) 45*s*.

THE inquiry carried out by Dr. East and his collaborators on Borstal boys is by far the most important official study of its subject, and appears at an opportune moment when the general public in Great Britain is much exercised over the alleged increase of delinquency among older lads. It carries forward, and in the main confirms, the earlier studies made of young delinquents of school age.

Between 1930 and 1937 nearly twenty-two thousand lads were received into Wormwood Scrubs prison, and examined in regard to fitness for detention in a Borstal institution. Of these, four thousand were made the subject of an intensive investigation. A medical officer carried out a detailed physical examination and applied tests of intelligence; and supplementary data were systematically collected from parents, police, probation officer and school. Unfortunately, as was almost inevitable, no comparable sample, drawn from the ordinary law-abiding population of the same age and the same social class, could be investigated at the same time, so as to obtain a control-group. To some extent the limitation is corrected by the possibility of comparing the conditions among those convicted for different types of crime or those committing crimes with different degrees of frequency. The causal factors observed are classified under the headings that are now usual in such investigations; and the statistical significance of the differences found has been checked throughout by the appropriate chi-squared test.

The discussion of the results obtained begins with a survey of factors popularly supposed to be 'hereditary'. A family history of crime was reported in 5 per cent of the cases: it was somewhat more frequent among those convicted of offences against property and those with more than one conviction. A family history of insanity was found in 3 per cent: such a history was found more frequently among those convicted of sex offences, but was no more frequent among those with more than one conviction than among the remainder. A family history of psycho-neurosis was found in only 2 per cent; and "no significant result emerged from this aspect of the investigation". So far, therefore, hereditary factors would appear to play but a minor part.

Among environmental factors, the home conditions of the delinquent proved, as usual, to be of supreme importance. The average size of the families from which these young offenders were drawn ("5 children alive including the boy himself") was appreciably larger than the average size of comparable families in the population as a whole. There was, too, a significant association between the absence of one or both parents (particularly of the father), or the departure of an older brother or sister from the home, and the commission of multiple offences against persons or property. The presence of quarrelsome relatives, and particularly of quarrelsome parents, appeared to be a not uncommon factor where the offences had been committed against persons or against discipline. Lads under lax, careless, or repressive control, and lads who had lived away from home, showed a greater tendency to repeat offences.

Owing to the limitations of the inquiry, little evidence was available on the connexion between crime and poverty. It was noted, however, that convictions for sex offences were less common among lads coming from the poorer districts. The total percentage of time spent by these lads in unemployment was not apparently any greater than that so spent by the general population of the same sex and age; but at the actual date of committing their offences a large number were temporarily unemployed. Between high earnings and multiple convictions a well-marked association was observed; and Dr. East directs attention to the paradoxical conclusion that seems to follow: "attributes which determine a lad to commit multiple offences (initiative, aggressiveness, selfishness) may sometimes favour his earning capacity".

Turning to the personal characteristics of the lads themselves, we find detailed tables for bodily defects and diseases and for physical conditions generally. But, once again, inferences are difficult to draw owing to our ignorance about the prevalence of such conditions in the general population at this age. On the whole, as Dr. East points out, his data do not confirm Dr. Goring's conclusions, namely, that "thieves and burglars are inferior in stature and weight", and that "those convicted of violence are, if anything, above the average in general physique".

The psychological aspect of the inquiry was limited mainly, though not entirely, to the investigation of definite abnormalities. Nearly 4 per cent of the lads were found to be mentally defective—a proportion far higher than would be found among the general population; and of those who had attended primary schools, scarcely one half had succeeded in reaching the highest class. Dr. East rightly concludes that "the subjects taught in the ordinary elementary school must be made to appeal to this type of scholar, if his activities are to be directed into socially useful channels; and to do this it may be necessary to go outside the ordinary curriculum". On the temperamental side he draws a suggestive distinction between the more active and the more passive type of offenders, and points out that, when it comes to treatment, the latter often requires "little more than kindly guidance", while the more aggressive criminal needs "strict custodial supervision". Adolescent instability was a well-marked feature in many of his cases; but more specific abnormalities were comparatively rare: insanity and epilepsy, less than 1 per cent each, psychoneurosis only 1·4 per cent. What are so often regarded as mental abnormalities calling for medical investigation turn out to be merely exaggerated forms of the normal emotional changes that accompany puberty. "The importance of the biological aspect is shown by the fact that during adolescence certain inborn instincts, namely, those of sex, aggression, gregariousness, acquisitiveness and self-assertiveness, become more direct and importunate"; and, as the detailed classifications show, these characteristics "seem often to determine the direction which the criminal outburst takes". The notion, still popular with medical writers, that crime is a "form of illness" Dr. East most strongly repudiates; and here every psychologist will agree with him.

Of the practical conclusions deduced from this valuable inquiry, the most important is the need for further scientific study. In particular, a "centre for criminological research" is advocated, "from which special forms of research at other penal establishments should be directed".

CYRIL BURT.

THE PHYSICAL BASIS OF LIFE

Cytology and Cell Physiology

Edited by Geoffrey Bourne. Pp. xii+296+21 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1942.) 20*s*. net.

IT would be an interesting experience to obtain access to a contemporary review by an impartial music critic of the celebrated incident of "fiddling while Rome burned"; it might provide a helpful guide to the correct mode of approach to a volume composed, so the preface informs us, entirely during the 1940–41 air *Blitzkrieg* on Britain. The preface goes on to relate how bombs were probably audible during part of every chapter, that one essay was written in an air-raid shelter, another in railway trains, etc., until a reader may feel tempted to ask why, in these circumstances, were such difficulties not regarded as grounds for deferring publication? An answer to this can be given, but only after the book has been read, and it seems a pity that the producers themselves should have presented a work of scholarship to the scientific world in terms which suggest a peculiar form of A.R.P. Adverse circumstances can indeed provide an explanation for shortcomings, if such is required; but it is difficult to see that they can add anything otherwise to the scientific value of the result.

The book is actually a collection of essays by nine collaborators on a variety of topics almost all of which could be included under a heading such as aspects of cell structure and physiology in animals. Each essay has an introduction and most end with a conclusion. They could be read with equal profit in any order. The matter ranges from an eye-witness account of fertilization in a sea-urchin (p. 93) to the biochemical details of digestion in the grub of the clothes moth (p. 206); from the pure physics of protein monolayers (p. 58 *et seq.*) to the distribution of mineral components in the walls of the blood vessels of human patients suffering from arteriosclerosis (p. 179–82). A reader at the end of it all may be tempted to quote with respect to the book as a whole a sentence intended by its author to apply only to the last chapter (on pathological cytology), namely, that "the problems encountered in this survey have been many and varied, the gaps in our knowledge extensive, so that at the present time a synthetic discussion seems unprofitable", and to ask whether that was really the principal conclusion that the authors intended to convey?

In considering this question it is necessary to bear in mind not only the inevitable difficulties of composite authorship, but also the peculiar nature of the subject. It must be assumed that the larger problem to which this volume is intended to contribute is that of providing a physico-chemical description of cell structure and function. Such a description must ultimately entail the successful exploration of a region of space which is at present more inaccessible to observation than almost any other. The world of the microscope ceases to be visible at sizes below about a third of a micron; but the world made familiar by the ordinary tools of atomic physics and chemistry is not reached at once but only when the scale of significant distances has shrunk to the order of a few angstroms. The gulf between these two worlds may be gauged by the comparison that $1 \mu = 10{,}000$ A., and in this almost uncharted region lies the structural framework behind almost all cytological problems, including fundamental issues such as the physical basis of life. A reader (or writer) who underestimates the immense and inherent difficulties of the ultimate problem will court disappointment deservedly.

The part that composite authorship has played in the presentation of the subject in the present instance may perhaps best be made clear by more detailed enumeration of the topics dealt with. The more significant of these may be selectively listed as: some chemical principles of cytological technique; experimental methods of studying unimolecular films; the plasma membrane; mitochondria and Golgi apparatus; some points of chromosome structure; microincineration; pathological cytology (including cancer). Clearly the synthetic discussion of all this material could only have been effected, were it possible at all, by one mind writing, and its absence here must be accepted as inevitable. The general impression conveyed by the book as a whole cannot therefore have been the principal object of writing it.

Composite authorship, on the other hand, has the merit, perhaps its only one, of making possible a more detailed and authoritative presentation of a greater variety of aspects of the main theme than can normally be supplied by one person. This is the case here. No single reader is likely to be equally versed in all the topics dealt with and something new and useful can scarcely fail to be learned by anyone interested enough to read the book carefully. Some things could, however, have been improved even within the selected framework. Thus the general inadequacy of representation of the botanical point of view is very obvious to a botanical reader, and is to be regretted in that, for some at least of the topics dealt with, botanical literature preponderates. This is conspicuously true for subjects such as protoplasmic permeability and spiral structure of chromosomes. In other places a timely reference to a plant, such as to the Fucus egg in connexion with artificial parthenogenesis, might have modified a general statement, while recognition of the relevance of some fields of plant pathology to an intractable cytological problem such as that of cancer would have enriched the book.

Another characteristic which may be expected to deter a reader from casual perusal is perhaps merely the reverse side of the book's most obvious virtue. In the attempt to overcome the undoubted difficulties of compilation, much of the matter tends to have been compressed together in a form closely resembling a catalogue. This may have its justification if completeness is thereby attained, but much is lost both in coherence and in power to stimulate thought. To quote one example, the work on the tobacco mosaic virus, mentioned among other matters on p. 243, is commonly regarded as one of the most important recent developments in the whole of biology; but this type of emphasis must be supplied, if at all, by the reader. The reader, in the same way, will have to extract, with some labour, from the close-packed pages of physics and biochemistry, the few really cytological facts which they contain, or, conversely, he may list on a piece of paper those few facts of sufficiently authenticated physics and chemistry to be found in the cytological chapters. The material is there, but the labour must be his.

In spite of these drawbacks the book does succeed to a considerable extent in achieving what must be regarded as its real and immediate object. This is something far humbler than the synthetic review of any one main theme, and may be thought of as the presentation of a record or series of records of the state to which the selected topics had arrived up to and to a limited extent beyond the outbreak of war. In this it is successful in exact proportion to the degree in which the personal interests and work of each writer is or is not closely linked with his topic. Where sidelines have been introduced for the sake of an imaginary completeness the treatment may be so fragmentary that it were better omitted. A case in point is the discussion of the uses of polarized light on pp. 29, 30. Without any mention of important modern monographs, such as those of Schmidt (1937) and Frey-Wyssling (1935, 1938), or of the greatest work of an older generation, that of Naegeli (by which the micellar theory and the existence of crystalline properties in organic materials was first deduced), such a summary is almost worse than useless. On the other hand, the same writer on a later page has produced a highly interesting account of the nature of the cell surface as he sees it, which is valuable to the reader chiefly because the point of view (though not of course all the facts) is the writer's own and based on personal experience.

The fact that quite a large part of this book could be described in the latter terms is the best tribute which can be paid to it and one which sufficiently explains its publication in spite of difficulties. Deferment would not have improved it since the effects of cessation of international intercourse will be felt more and more as long as the War lasts and the difficulties of collating literature will not grow less. As a serious contribution to cytological literature this book deserves a place in every scientific library.

One word of kindly advice may, however, be offered to the cytological civilian who may have to face a new *Blitzkrieg* in 1942–43. Let him take this book with him into his dugout by all means, but let him also take two other volumes, namely, Gray's "Textbook of Experimental Cytology" (1931) and the Cold Spring Harbor Symposium on Nuclear Biology (1941). These will provide relaxation from the more solemn tasks of A.R.P. and remind him of the happier days when Rome was not on fire.

I. Manton.

NEW LIGHT ON THE APOCALYPSE OF ST. JOHN

The Book of Revelation is History

By H. S. Bellamy. Pp. 204. (London: Faber and Faber, Ltd., 1942.) 8*s*. 6*d*. net.

Mr. BELLAMY'S interpretation of the Apocalypse is entirely cosmological, being based upon the theory of the Austrian, Hoerbiger, concerning the attraction and ultimate destruction of satellites. Mr. Bellamy discovers in the Book of Revelation three cycles of myths, all concerned with a most appalling cataclysm which occurred thousands of centuries ago —the attraction and disintegration by the earth's gravitation of the satellite which was the predecessor of our present moon. He discovers further mythological material which he traces to a subsequent cataclysm which occurred when the planet Luna was captured by the earth's gravitation about fifteen thousand years ago, causing the sudden submergence of the continent of Atlantis.

The editor of the Apocalypse, says Mr. Bellamy, must have derived his knowledge from some esoteric source, either on the isle of Patmos where he went "for the word of God", or from some other source which the name is used to conceal. The first myth (Rev. i, 1–20) is a general survey of the scene before the disintegration began. The satellite would at this time appear to be very near the earth and brilliantly lighted. Thus a group of brilliantly lit craterlets might well seem to be a group of stars, and the face of the satellite would almost certainly be covered with grotesque shapes. The second myth (iv, 1–8) is a series of observations of these, in which the imaginative eye sees them as the four-and-twenty seats, the elders, and the beasts "who rest not day or night". The "sea of glass like unto crystal" indicates the glaciosphere of the satellite. When the disruptive pull of terrestrial gravitation began to outweigh the internal cohesion of the satellite, this glaciosphere would crack and split into slabs. These slabs would crowd towards the apex so that new forms, for example a 'lamb', a 'book', a 'throne', might appear. The actual beginning of the disintegration is seen as the 'opening of the seals'; then follows the account of the disintegration proper under the symbol of the sending forth of the four horses. The white horse signifies the white, or icy, stage, the red horse the ensuing stage in which the glaciosphere is entirely stripped away revealing the red soil beneath, the black horse the bare metallic core of the satellite, which under disintegration would shine livid in the light—the pale horse. The rain of blood is the fall of the red soil, and the star which fell from heaven opening the bottomless pit (ix, 1,2) a huge meteorite which pierced the terrestrial crust of the earth and penetrated to the magmatic strata beneath. Mr. Bellamy traces other references to this breakdown cataclysm in appendixes on Ezekiel, Ezra, Enoch, and others.

Mr. Bellamy identifies "mystery Babylon" with Atlantis. "The great πολις was found no more, because this angel had thrown into the sea a huge white round object, like unto a mill-stone" (Rev. xviii, 21). Again quoting from the book of Ezekiel, "How art thou destroyed that wast inhabited by seafaring men, the renowned city that was strong in the sea. . . . Now shall the isles tremble in the day of thy fall; yea the isles that are in the sea shall be troubled at thy departure" (xxvi, 17–18). Space does not allow more than a reference to these survivals of Atlantis myths which the author traces.

Supposing this explanation to be scientifically probable, why should the editor of the Apocalypse have attached such religious importance to so purely cosmological a chronicle? The author makes the interesting observation that he lived at a time of great crisis when established codes of behaviour were losing hold of the masses, as at the present day. His work may therefore have been an attempt to show the relationship between religion and science, so as to disentangle religion from crumbling conventionalism. He may have been trying to use the history of these cataclysms to reveal the hidden relationship between the inner lives of individuals and the lives of nations and of the world, so as to dissolve the dividing wall which current ethics would set between the scientific and religious points of view. Such a book, then, while justly claiming absolute truth, would admit of different interpretations according to the religious development of the reader; for the fact that heaven and hell may be cosmologically interpreted does not preclude other interpretations on different levels of consciousness. The dead are still burying their own dead, and the living are still being led unscathed through the ten circles of hell.

B. M. B.

RELATION OF MINERAL RESOURCES TO WORLD PEACE*

By Sir THOMAS HOLLAND, K.C.S.I., K.C.I.E., F.R.S.

AMONG the raw materials referred to in the Atlantic Charter minerals are, beyond question, the most important because of their natural occurrence under fixed geographical conditions which cannot be changed by any artificial measures. They are essential to all technical industries; and, rightly or wrongly, applied technology has become an inevitable and ineradicable phase of our civilization. No civilized community can now exist without a sufficient, and sufficiently varied, supply of mineral products; substitutes for them cannot be provided, except to a very small degree, by other materials, natural or artificial, without increased cost and loss of efficiency. The demand for them is insistent and certainly will increase in the immediate future. The problems before us are therefore urgent.

Yet the workable deposits of useful minerals are distributed without regard to climate or established national boundaries. It follows, consequently, that, so long as difficulties are created among the nations for the exchange of such raw materials, there must always be potential friction between the 'haves' and the 'have nots'. One can even go further without intelligent contradiction and say that, whereas tariffs can hamper international trade in mineral products, no tariff can prevent the trade altogether without the immediate creation of conditions which are certain to lead to war.

It will not be possible here to do more than present one or two illustrations to show the importance of selecting this section of the Atlantic Charter for special discussion; and this limitation to mineral questions does not mean that we fail to recognize the similar significance of other raw materials.

But it is the speed of change in the international bearing of mineral questions which gives them special urgency. During the first thirty-seven years of this century, the output of ordinary steel in the United States increased five times, from about 10 to more than 50 million tons, and, to produce the output for 1937, three fourths of a million tons of manganese ore had to be imported as one constituent among the necessary raw materials. In the latter year, with the help of a protective tariff amounting to about 100 per cent of the import price of manganese ore, the United States did not produce enough of the ore from domestic sources to meet much more than about five per cent of that country's own essential requirements. (In giving these round figures I am not unmindful of the fact that research on methods for concentrating the large deposits of American low-grade ores shows some signs of possible success in times of high prices or during the emergency of war.) You can guess therefore what the result would be if an extension of the recent tendency towards nationalism went so far as to prohibit the export of manganese ore to the United States from the four or five principal sources—the British Empire which then produced one third of the world's total of six million tons, and Russia which produced another third, both countries, especially Russia, wanting a large share of their own outputs; while France, Germany and Japan, producing between them negligible amounts, wanted most of the remaining third.

Short of absolute prohibition, tariffs might conceivably force the United States to exploit more vigorously its own resources at home and in Cuba, with the result, however, that all known workable high-grade resources at the disposal of the American Government would be effectively exhausted within a few years. The world is so made that the chief steel-making countries—the United States, Great Britain, Germany, France, Italy and Japan—have little more than negligible resources of manganese ore to rely on within their own political boundaries, whereas the countries in which the mineral occurs in greatest abundance are but small consumers of it. During 1937, four fifths of the world's output of steel occurred in countries which produced only about two per cent of the required manganese[†].

India is now producing about a million tons of steel annually, but uses for the purpose less than two per cent of its own output of manganese ore. Russia thus becomes an outstanding exception; for many years it has been the world's chief producer of manganese, and, unexpectedly to others, during the decade before 1937 increased its output of steel ten times, thus passing from the sixth to the third position among the steel-making countries.

Now we can speculate with some degree of certainty on one important reason why Germany suddenly broke her pact and invaded Russia. It is a prospective shortage of manganese rather than of petroleum which threatens disaster to Germany's munition supplies. Petroleum can be made to some degree and to an increasing extent from the abundant brown coal supplies in Germany itself, although this incurs the absorption of much technical man-power, and nearly sufficient natural supplies are obtainable from other controlled countries, especially Rumania. But of manganese, all the European countries under the domination of Germany cannot together produce more than a fraction of that necessary to feed the steel furnaces under German control. Before the War the countries now under German domination imported annually more than 1½ million tons of high-grade manganese ore. The most productive among them has never turned out a tenth of this quantity, and even that is of a relatively low grade. Before the War of 1914–18, both France and Germany had accumulated some stocks of manganese, but not nearly enough to see them through, and Germany, being hampered at sea, was finally in serious difficulty.

One cannot, however, be confident in estimating the stocks of manganese still available in countries now under German control, because, while there is evidence that Germany herself was very late in commencing to accumulate stocks of imported ore for emergency use, it is obvious that France began soon after 1922 and continued annually to import far more manganese than was necessary for her output of steel[‡]. This is but one of the many ways in which the French people and their Allies have been 'let down' by a few of their weak and treacherous political leaders.

Whatever doubt on this account there may be about Germany's access to reserves of manganese, one can be more certain about her anxiety to exploit some others of the varied mineral resources of the Soviet, and one of these is almost certainly the

---

[*] Substance of the opening address at the Conference on "Mineral Resources and the Atlantic Charter" of the Division for the Social and International Relations of Science of the British Association on July 24–25.

[†] Roush, G. A., "Strategic Mineral Supplies" (McGraw-Hill, 1939), p. 38.

[‡] Roush, G. A., *op. cit.*, p. 68.

relatively rare metal platinum, which is wanted in fairly large quantities for various war industries as well as for the manufacture of nitrous explosives. Although the output of the precious metal has trebled during the past twenty years, the substantial sources of supply are still under the control of the united democratic nations, Canada producing about a half, Russia about one fifth, America and South Africa between them another fifth, supplemented by smaller quantities from the Republic of Colombia, Belgian Congo and Abyssinia.

The argument which I have used, based on our information about the natural distribution of manganese ore in the world, is no lonely illustration of the fact that the occurrence of mineral raw materials does not coincide even approximately with the national domains in which industries have been most highly developed. There are others of a similar type on which the continuance of present civilized activities are dependent, and the American Government, wisely listening to its scientific and technical advisers, has labelled a dozen such minerals, on this account, as strategic, that is, minerals on which the United States depend on outside—sometimes distant—sources, for those supplies which are absolutely necessary to maintain essential industries and therefore to ensure safety in defence.

Manganese came into general use soon after the invention of the Bessemer process in the middle of the last century, and well over 90 per cent of the metal produced in the world is now consumed in steel-smelting. Although the metal is thus consumed only in a way analogous to that of a medicine, there is no known substitute to take its place on a large scale, and so under present war conditions it becomes a 'key' product.

But out of the study of its function in this way, there arose some twenty-five years later a quite different use for the metal as a definite constituent of the manganese-steel which was invented by the late Sir Robert Hadfield. His invention of manganese-steel opened up a new era in metallurgy, for it became the forerunner of a whole family of alloys of iron with relatively rare elements like cobalt, chromium, molybdenum, nickel and tungsten.

It was the discovery and extended use of these new alloys which changed, and changed on a large scale, the problem of supplies for the industrialized Great Powers. In the last century mechanical industries sprang up around areas containing deposits of the small number of natural products required in the manufacture of ordinary iron and steel; for example, around the British coalfields, in which there occurred associated supplies of iron ore, limestone flux and coking coal. When the local supplies of ore became exhausted, improved transport facilities enabled Great Britain to bring iron ore from Spain and Scandinavia. But then again when ferro-alloys, with their very special and previously unexpected properties, superseded ordinary steel, their constituents had to be brought from still more distant parts of the earth, and the whole problem of commercial success in industry, as well as security in war, thus assumed an entirely new configuration. For, in addition to the family of ferro-alloys, other metallic alloys of industrial importance were discovered, such as those largely made of aluminium and magnesium, combining low density with sufficient strength for aircraft construction. Nor indeed is the end of this avenue of metallurgical development in sight or even predictable.

A country like Great Britain, which was practically self-contained for the few and simple essential constituents of ordinary steel up to the last quarter of the nineteenth century, quickly found itself dependent on supplies from distant parts of the Empire, and even from foreign competitors. From the happy condition of congratulating itself, the new century found Great Britain, for example, looking to Canada and the Belgian Congo for cobalt, to British Guiana and France for aluminium ore, to Canada for nickel, to India and the Gold Coast for manganese, to China and Burma for tungsten. A new meaning was given to the importance of retaining command of the seas, which seems now to be giving place to command of the air.

These are but a few among many mineral products which are just as essential as imported food for our continued existence as a nation; and indeed more so, because no artificial effort can grow minerals where they have not been placed already by Nature. There are not and never will be available synthetic metals for industrial use. We can use plastic products for door knobs and ash trays to economize in imported copper and zinc for brass, but we cannot economically replace bauxite, which we must import for its aluminium, by aluminous clay which we have in abundance; and generally, while one metal can occasionally be used to replace another at greater cost and reduced efficiency, so far as Great Britain is concerned, we cannot produce even an inefficient substitute. But Great Britain is not unique in this respect. France, Germany, Italy and Japan, as independent units, are also dependent on the outside world in other ways and to different degrees. Even the United States can never be self-contained. Nor can any country derive comfort and security from its greater approach to self-sufficiency; for what is the use of being able to build a motor-car if we are dependent on another country for a sparking-plug?

So far I have spoken of essential minerals in qualitative terms. When we consider the situation quantitatively, the problem takes a much more serious aspect. The extension of our demands in kind is being accompanied by a correspondingly increased consumption in quantity, with one immediate and dangerous result that smaller deposits of useful minerals must be neglected for richer and larger masses which can be exploited in bulk. The pace in consumption has increased since 1900 on a scale which has resulted in a greater output than the total production of all previous history back to the Stone Age.

This comprehensive statement has been met, I know, with the criticism that statistical records do not extend back beyond the nineteenth century; but its accuracy can be checked by a simple diagram for any representative mineral used in the industrial arts and therefore can be applied to the whole. We might, for example, take a metal like copper as one which is familiar to everyone by its widespread use in a variety of ways. At the beginning of the nineteenth century the world produced about 10,000 tons of copper a year, by the middle of the century about 40,000 tons, and before the century finished, production had reached half a million tons annually. The curve of production went on rising, with only two serious setbacks, until it indicated in 1937 that the annual output had passed two million tons. It is easy to see that the area of the curve enclosed between 1900 and 1927 must necessarily exceed that of all previous periods since man became a metallurgist. Similar curves, not always rising so steeply, tell the same story for other familiar metals.

This matter is not mentioned as a mere curiosity of industrial history: it is to show that, with the growth of national exclusiveness in recent years, there has sprung up an increased interdependence among the nations and especially among the greater Powers, beyond the control and, one can say with safety, beyond the mental comprehension of those politicians who have had most to say, and too much influence, on the international questions which have brought us to the present condition of universal war.

As one result of vague fears of aggressive trespass during the past twenty years, and in spite of isolated attempts to the contrary, the nations have become more and more self-conscious, and, with regard to their natural possessions of minerals, more inclined to conserve their resources. Many of them, the British Empire no less than others, have refused the grant of concessions to prospect for or to exploit mineral deposits, thinking through vague fear that some vital asset may thus be squandered; forgetting, however, that a mineral deposit cannot in an emergency be readily turned to account by the nation itself unless it is already developed, overlooking the fact that, even under war conditions, a mine cannot be taken out of the country in which it lies, and failing to realize that what matters is not the nationality of the mining company which risks its money in prospecting and mining, but in which country the mineral is finally prepared for use in the arts—the arts of peace or the arts of war.

Failure generally to appreciate the fact that civilization cannot go on at all without the international exchange of minerals has developed at times a general atmosphere of tension that cannot be relieved except by war. As no country can ever be self-contained in future for essential mineral raw materials, no nation can contribute its share to the progress of civilization without the operation of principles such as those outlined in the Atlantic Charter. But for democratic nations to implement those principles, it is necessary for the public to understand far more than they do now the part which mineral problems play in civilized activities.

In the United States the problems have been examined in critical detail for several years by selected committees of technological specialists, but naturally their chief object has been to provide military security for the nation in a world threatened by potential aggressors.

The Soviet Republics of Russia have done the same by official organizations, and most of the world seems so far to have failed to appreciate the extent of their resources or the realistic thoroughness which has actuated the present Government of the U.S.S.R. in the utilization of applied science.

Fifteen years ago, the British Empire Council of Mining and Metallurgical Engineers formulated proposals for a similar investigation of our scattered resources, but the Dominion Governments have apparently been dominated by the immediate problems of promoting inter-Empire commerce, and have consequently overlooked the dangers of national exclusiveness regarding mineral raw materials, which all well-behaved nations must reasonably obtain if civilization, such as we know it, is to survive.

At the time of the South African meeting of the British Association, I could see no further than a possible understanding—which is the first necessary step towards agreement—between the United States and the British Commonwealth, which between them, at the time, controlled three fourths of the world's workable deposits. My imagination takes me in the same direction still, but very little further along the road towards the development of an international conscience about the hoarding of mineral deposits.

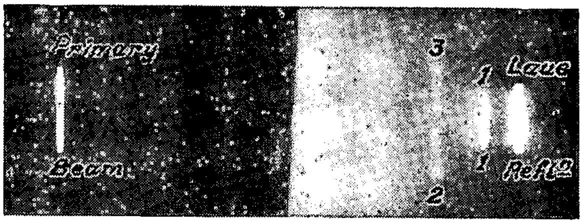
Another serious effort should be made to formulate measures for facilitating the international flow of mineral products, keeping always in mind the simple circumstances that no country is or will be self-contained for mineral supplies, and no development of science can or ever will grow workable mineral deposits where they are not already formed by Nature. And I ought perhaps to repeat what I suggested at the beginning, that this question is by no means a matter of academic interest. It is one that must be settled and settled quickly by practical measures if civilization is to be saved for our descendants. Unless it is settled, and settled quickly at the end of the War, by an intelligent understanding among the successful Powers, newly concocted aggressive attempts to enforce control will lead intermittently to further outbreaks of war. Delay for more mature consideration may be the rashest step to take.

REFLEXION OF X-RAYS WITH CHANGE OF FREQUENCY

By Sir C. V. RAMAN, F.R.S.

Indian Institute of Science, Bangalore

In *Current Science* of April, 1940, photographs were published exhibiting the very remarkable phenomena observed when a pencil of X-radiation from a copper target traverses a cleavage plate of diamond and the resulting Laue diagrams are recorded with adequate exposures. The photographs showed monochromatic X-ray reflexions from the (111) planes of the crystal which were quite sharply defined at all settings of the crystal but which were evidently different from the well-known Bragg reflexions. As this phenomenon was inexplicable on the existing X-ray theories, it was interpreted as follows: X-ray photons traversing a crystal can exchange energy with it, giving up or taking on a quantum of energy corresponding to the frequency of one or another of the infra-red or high-frequency vibrations of the crystal lattice; the X-rays are then geometrically reflected by the lattice planes of the crystal with a change of frequency. Further study of the effects exhibited by the (111) planes of diamond showed them to be in complete accord with the ideas outlined in the article of April, 1940 (see accompanying



Triple quantum reflexions by the (111) planes in diamond.

illustration). If the fundamental process stated is possible with diamond, it should also occur and be observable with other crystals. Investigations were made which showed that this is actually the case; these are described in a whole series of papers published in the *Proceedings of the Indian Academy of Sciences* and in *Current Science* from May, 1940, onwards.

The purpose of this article is to present a general account of these investigations, and in particular to show how the reality of the frequency changes in X-ray reflexion has been demonstrated and their magnitude determined from intensity measurements at various temperatures.

Earlier X-Ray Theories

The fundamental X-ray process stated above presents a formal analogy with the scattering of light in crystals with change of frequency discovered by me in 1928, except that we have a geometric reflexion of the X-rays instead of the diffuse scattering observed with ordinary light. Why the possibility of such a process is not indicated by the existing X-ray theories is a point of some interest. In this connexion, a memoir by Laue (1926) in which he discussed the effect of the thermal agitation on X-ray propagation in crystals is well worthy of study. Laue showed that assumptions of the most divergent character regarding the nature of the thermal agitation in crystals lead to closely analogous expressions for the temperature factor in the intensity of the ordinary X-ray reflexions. Hence, even a reasonably good fit of the temperature factor with the experimental facts in selected cases cannot be regarded as evidence that the theoretical assumptions from which it is derived correspond with reality. The position is, in fact, closely analogous to that arising in the theory of specific heats, where very different formulæ (Nernst-Lindemann, Debye, Born-Karman) all fit the facts in certain simple cases fairly well.

A completely different situation arises when we consider the secondary radiations from the atoms which do not appear in the direction of the usual geometric reflexions. Here, as Laue remarked, the changes of frequency arising from the oscillations of the atoms are of fundamental importance, since only radiations of absolutely identical frequency can reinforce or cancel each other by interference. Hence, the spectroscopic properties of the crystal are of the very essence of the problem. If, therefore, we start off with assumptions regarding these properties which do not correspond with reality, the deductions therefrom will equally fail to represent the truth. This, actually, is the situation of the Faxén–Waller theory of X-ray diffraction in crystals, which rests on Born's postulate of the cyclic lattice. Born's crystal dynamics is based on the same idea as the specific heat theory of Debye, namely, that the distinct frequencies of atomic vibration in a crystal are as numerous as the atoms themselves and accordingly form a continuous spectrum. This assumption is contrary to the experimental facts of spectroscopy. Several distinct methods of spectroscopic research agree in indicating that a sharply defined monochromatism of the frequencies of atomic vibration in the near and remote infra-red is characteristic of the crystalline state; for the same reason and to the same extent that a perfect three-dimensional periodicity of the static arrangement of the atoms in space is characteristic of crystals.

Dynamic Reflexion of X-Rays

If, following Debye and Born, we assume that the frequencies of atomic vibration are as numerous as the atoms themselves, it follows immediately that the secondary radiations arising from such vibrations have correspondingly numerous frequencies and are therefore incapable of reinforcing each other by interference. The effect of partitioning the mechanical energy of vibration into a very large number of distinct frequencies is also to reduce the energy of any particular vibration to vanishingly small proportions. Further, the vibrations of higher frequency would have relatively the smaller amplitudes. Hence on the assumption stated, no distinctive effects could be expected from the high-frequency vibrations, in spite of the fact that practically all the available degrees of freedom of atomic movement are necessarily associated with such high frequencies.

That the Debye-Born concepts of crystal behaviour are unreal is, however, evident from the spectroscopic data. For example, Bhagavantam (1930) found that the spectrum of monochromatic light scattered in diamond exhibits an extremely intense and perfectly sharp line with a frequency shift of 1,332 wave numbers, besides several other feeble lines with both larger and smaller frequency shifts. Nayar (1942) studied the blue fluorescence spectrum of diamond and the corresponding absorption spectrum in the near ultra-violet. On immersing the diamond in liquid air, these spectra appear resolved into discrete lines. The frequency shifts of these lines from the electronic band at 4152 A. common to both absorption and fluorescence were found to be positive for one and negative for the other, but otherwise absolutely identical. Nayar was thus able to discover and measure nineteen discrete frequencies in the lattice spectrum of diamond, ranging from 1,384 to 176 wave-numbers per centimetre. Considering the simplicity of the crystal structure of diamond, these facts can only be regarded as a direct experimental refutation of the Born dynamics.

We are therefore justified in rejecting the existing X-ray theories and striking out on a new path which has as its starting-point the observed monochromatism of the infra-red vibrations in a crystal. Each of the observed discrete frequencies of vibration is necessarily associated with a very great number of degrees of freedom; in other words, it represents a mode of vibration occurring similarly and simultaneously in great numbers of the lattice cells, if not in the entire crystal. Such a vibration would give secondary radiations of altered frequency having their origin in the cells of the lattice and having coherent phase-relationships: these would therefore be capable of reinforcing each other and giving a notable intensity in the direction where they agree in phase and a negligible intensity in other directions, in a manner closely analogous to that in which the ordinary Bragg reflexions of unmodified frequency arise. Complete identity of phase of the vibration in all the lattice cells would make the dynamic reflexions observable only in the same crystal settings as the Bragg reflexions. The spectroscopic facts, however, do not appear to demand such a rigorous identity of phase of the vibrations in all parts of the crystal. It may therefore be assumed that a certain variability of the phase is permissible; this idea is given concrete expression in the concept of phase-waves or planes of constant phase for the infra-red vibrations. The possible orientations of these phase-waves would depend on a number of considerations, including especially the structure and symmetry of the crystal and the particular mode of vibration under consideration; such considerations, therefore, also determine the geometric law of the dynamic reflexion.

In view of the change of frequency, we must necessarily regard dynamic X-ray reflexion as involving exchanges of energy between the X-ray photon and the crystal, analogous to those observed in the scattering of light. It follows that the temperature dependence of the intensity of dynamic X-ray reflexion should be of the same general nature as that indicated by the principles of the quantum theory for the scattering of light in crystals with altered frequency. The important difference is that, in the X-ray case, we can only observe the summation of the effects appearing with enhanced and diminished frequencies. Taking note of this, it follows that the reflexions associated with vibrations of high frequency should show a relatively small temperature variation and reach their limiting intensity at moderate temperatures; on the other hand, reflexions associated with vibrations of low frequency should show a more marked temperature dependence and reach their limiting intensity at a very low temperature.

Observations with Diamond

The verdict of the spectroscope which compels us to reject the Debye-Born concepts of crystal behaviour is independently confirmed by the X-ray phenomena. In particular, the effects exhibited by diamond are of such a striking character that they are in themselves a complete refutation of the Born crystal dynamics and *per contra* confirm the essential correctness of the new ideas outlined above. The octahedral planes in diamond are equally inclined to the three cube faces of the crystal. If, therefore, the phase-waves for an oscillation of the alternate layers of atoms in the octahedral planes against each other along the common normal are parallel to one of the cube faces of the crystal, symmetry demands that phase-waves parallel to the other two cube faces should also exist and give dynamic reflexions by the same planes. Further, it is known that such an oscillation has a high infra-red frequency, namely, 1,332 wave-numbers, and that a line with this frequency shift appears in light-scattering with an intensity sensibly independent of the temperature. The X-ray observations show, in agreement with the new idea, that the (111) planes give, in general, three geometrically sharp reflexions which appear in positions which are in perfect accord with the phase-wave formula (see accompanying illustration) over the entire range of crystal settings in orientation and azimuth. Their dynamic character is shown by the fact that the angular separations of the reflexions from the primary beam are not invariable but alter with the setting of the crystal. Further, the intensity of these reflexions scarcely alters with temperature over a wide range from that of liquid air upwards. The intensity of the reflexions diminishes rapidly with diminishing phase-wave length, but neither their perfect sharpness nor their temperature invariance is influenced by an alteration of crystal setting.

The facts stated above are obviously impossible to reconcile with the belief that they arise from vibrations of the elastic solid type having a thermal origin. The supporters of the thermal-elastic theory of X-ray diffraction appreciate this difficulty and have therefore adopted the expedient of trying to remove it by various *ad hoc* hypotheses, for example, that "a strain which is cubic in symmetry is inherent in the majority of diamonds", or that "diamond is not a normal crystal". It is sufficient to remark that suggestions of this kind do not explain the observed facts and that they are physically meaningless. In an article on the physics of the diamond just published (*Current Science*, July, 1942), I have shown that these and other beliefs which have been expressed in recent physical literature about the diamond are without any foundation in fact. Limitations of space prevent a consideration here of further problems which arise, namely, the other modes and frequencies of vibration of the diamond lattice, the X-ray effects exhibited by other lattice planes and the influence on the X-ray phenomena of imperfections of crystal structure when such are actually present in diamond. A discussion of these questions would greatly lengthen this article without really helping to clarify fundamental issues.

Measurement of the Frequency Changes

Whether, in specially favourable cases, X-ray spectroscopy may succeed in directly exhibiting the frequency-changes which arise in the dynamic reflexion of X-rays is a matter for future research. Fortunately, however, the reality of these frequency changes may be demonstrated and their magnitude determined by a very simple method which is of universal application. The method depends on the fact that, according to the principles of the quantum theory, the temperature variation of the intensity of these reflexions depends on the frequency of the lattice vibrations responsible for their production. According to the present theory, this frequency would be independent of the setting of the lattice planes giving the reflexions. On the other hand, in the Faxén-Waller theory of "diffuse thermal scattering of X-rays", the reciprocal of the elastic wave-length and therefore also the frequency of the vibrations giving the "diffuse maxima of scattering" which appear in that theory vary with the setting of the crystal and may be given any desired small value by making the crystal approach the Bragg position sufficiently closely. By holding the crystal in such a position and lowering its temperature to that of liquid air, the "diffuse maximum of scattering" should then diminish in intensity nearly in proportion to the absolute temperature. Tests of this kind have been made at this Institute with diamond by Dr. Nilakantan (1940) and with numerous other crystals (carborundum, rock-salt, sodium nitrate and penta-erythritol) by Dr. Venkateswaran (1941). The experimental results are decisive against the Faxén-Waller theory and show in an unmistakable way that the high-frequency or infra-red vibrations of the crystal lattice and not the low-frequency or elastic vibrations are responsible for the observed dynamic reflexions.

X-Rays and the Infra-Red Spectrum

It is not to be expected that weak and imperfect crystals, for example, soft metals, organic crystals and the like, would give at ordinary temperatures dynamic reflexions which are as geometrically sharp as those observed with diamond. Nevertheless, the published observations with such crystals show that the half-widths of the "diffuse spots" are in many cases, for example, hexamethylene tetramine and urea nitrate, only a small fraction of the separation of the spots from the Laue reflexions and alter but little with the setting of the crystal. These facts clearly indicate that the reflexions observed do not owe their origin to vibrations of the elastic type.

Apart from the points dealt with in the foregoing account of the subject, there is much experimental evidence of a different nature on record which supports the validity of the new approach to X-ray theory made by the present writer. To appreciate fully this evidence, one must be familiar with both the X-ray and the spectroscopic literature. The remarkable way in which the X-ray results illuminate and are illuminated by the facts of spectroscopy will then be evident. In particular may be mentioned the correlations which exist between the geometric characters of the modes of infra-red vibration, especially those of low frequency, established by spectroscopic studies on light-scattering, and the observed intensities of the dynamic X-ray reflexions by the various lattice planes in the crystal. Such correlations are particularly striking when the molecules or ions in the crystal have planar configurations, and their translational and rotational oscillations have low frequencies (as is generally the case); the crystal planes nearly parallel to the ions or molecules then give intense dynamic X-ray reflexions.

NEWS and VIEWS

Scientific Exhibition in Moscow

An exhibition devoted to the cultural relations between the University of Moscow and the universities and scientific institutions of Great Britain and the United States is now open in one of the halls of the University, where the bomb damage suffered in an enemy raid last year has now been made good. The exhibits include many editions of the scientific works of Faraday, Clerk Maxwell, Scott and others, and correspondence between British and American men of science and members of the Russian Natural History Society. Of special interest is a section reflecting the scientific relations between Russian and British scientific workers. There is the unpublished correspondence between Lord Kelvin and Prof. Umov, who was an honorary member of Cambridge University. There is also a selection of letters exchanged between British and American botanists and zoologists. One of the exhibits is a photograph of the famous Russian naturalist Timiryazov wearing the robes of a doctor of the University of Cambridge.

A section devoted to Charles Darwin contains his correspondence with Russian men of science, and a copy of a book written in support of his theories by the Russian zoologist Mensbir, who was one of the first to defend them. Copies of Russian translations of Darwin's works are shown, together with material from the many celebrations in honour of the great British naturalist which have been held in the U.S.S.R. from time to time. Exhibits illustrating the work of Moscow savants who have lived and worked in the universities of Great Britain and the United States are a special feature. One of those is Prof. Pavel Vinogradov, who has made the medieval history of England and Italy his special subject. He worked for some time at Oxford, and was honoured with a knighthood by the British Government. His colleagues elected the aged Sir Paul Vinogradov to the responsible post of chairman of an international commission charged with the preparation of a new edition of a dictionary of medieval Latin.

Other figures to which prominent reference is made at the exhibition are Prof. Peter Kapitza, who has been closely connected with both Soviet and British academic life, Pavlov, Prof. Samuel Harper, of the University of Chicago, and Sir Bernard Pares, of the University of London. A large section is devoted to the exchange of books between the University of Moscow and the principal universities of Europe and America. During the past two years the University of Moscow has received more than 4,500 scientific publications from 320 cities throughout the world.

Cultural and Scientific Mission in China

Dr. Joseph Needham, F.R.S., of the Cambridge Biochemical Laboratory, has recently accepted a mission of cultural and scientific co-operation, on behalf of the British Council, to China. In Chungking he will be attached to the National Academy of China (Academia Sinica). He will carry letters of greeting to Academia Sinica from the Royal Society and the University of Cambridge, and to other Chinese organizations from the appropriate British bodies. He expects to visit most of the Chinese universities, and to facilitate the supply of scientific apparatus and books from India with the help of the Indian Government. It is probable also that he may be able to help the interchange of scientific and technical information between China and the other United Nations. For this purpose he would be glad to receive any suggestions bearing on the problems of scientific liaison, or any questions of specifically Chinese relevance; after the end of the present month, he may be reached c/o British Embassy, Chungking, via Foreign Office, London.

Man-Power in Physics in the United States

The War Policy Committee of the American Institute of Physics has issued a report surveying the man-power problem in physics in the United States. It is stated that there are only 7,000 physicists in the United States, the large proportion of whom are doing vital war research. This leaves too few for the training of the large numbers of men needed for the operating and maintaining of technical mechanisms like aeroplane and submarine locators, signalling devices, anti-aircraft fire control, etc. The Committee estimates that some 200,000 men and women will require training in physics within a year. These will be mostly next year's college and university students, who expect to enter the Army or Navy reserve training courses to be carried out at these institutions, and they will have to be taught by staffs already considerably depleted for war research. The Committee urges therefore that every possible step be taken to increase physics man-power of the United States and to use the present supply in the most effective manner. It recommends the establishment of Government-sponsored teacher-training courses, the adoption of wise occupational policies by the Selective Service System, financial aid to qualified students so that they may continue and finish their studies (especially graduate students who are already taking a large part of the teaching load), and use of physicists in the Army and Navy only for work requiring their training. The Committee states that there is not sufficient understanding of the importance of physics in the war effort, especially on the part of the general public and of some local boards of the Selective Service. To remedy this, it is suggested that a public relations programme be commenced to educate the general public to the position, and to impress on students and teachers of physics the importance of continuing their work.

Control of Opium and Other Dangerous Drugs

MEETINGS in connexion with the international control in narcotics have just been held in London under the International Conventions concluded in 1925 and 1931. The Permanent Central Opium Board, which exercises, under the auspices of the League of Nations, the supervision over the manufacture of, and trade in, opium and other dangerous drugs in all parts of the world, has held its forty-first session. It was attended by Sir Atul Chatterjee, president (India), Mr. Herbert L. May, vice-president (United States of America), Sir Malcolm Delevingne (United Kingdom), Mr. J. H. Delgorge (The Netherlands), and Dr. George Woo (China). The Board carefully scrutinized the world position as it appears from the statistical reports sent in for the year 1941 by fifty sovereign States and some sixty-six dependencies and colonies and other territories. It also considered certain questions of policy and solutions of problems arising from the special circumstances of the War. Under the terms of the Conventions, the Board's report on its work is being sent to the Secretary General of the League of Nations.

The other international organization operating under the Conventions, namely, the Supervisory Body, has the task of examining annual estimates sent by Governments of their drug requirements, and members of it met for consultations to consider questions arising on the estimates for 1943, and issuing the Supervisory Body's annual statement on world requirements of narcotic drugs for that year.

Collaboration in the British Empire

THE Peter Le Neve Foster Lecture on "Empire Relations", delivered by Viscount Bennett before the Royal Society of Arts on June 3 (*J. Roy. Soc. Arts*, 90, 613; 1942), gives a lucid survey of the development of the relations between the parts of the British Empire from the sixteenth century to the organization of the present Imperial Conference system in 1907, when these conferences became a fixed method of consultation between the self-governing Colonies and Great Britain and one another. Mainly from a constitutional point of view, Lord Bennett gives an account of the further development of the system and its limitations, notably its failure effectively to promote Imperial development on scientific lines. Imperial conferences since 1907 have been concerned with almost every conceivable subject, including communications, patents, development of Empire resources, research, timber reserves, wool production, etc., but while they have afforded an opportunity for representatives of all the nations of the Commonwealth to meet one another and discuss personally Empire problems in the light of their experience and special knowledge of their own communities, they have led to no agreement upon any adequate method for providing continuous consultation on matters of common concern. Urging the need for an earnest effort to make the story of the Empire better known to the youth of Great Britain, Lord Bennett stresses the importance of providing the means for adequate and continuous consultation. This is essential for common action by the Governments of the Empire to attain a common end, and he suggests that a member of each of the Governments of the Overseas Dominions might be resident in London. Regular meetings between the Prime Ministers or representatives of their several Governments, utilizing air transport and with a permanent secretariat, might provide a solution of the problem.

A Proposed World Calendar

THE World Calendar Association, Inc., New York, has published details for a proposed new calendar to commence in 1945 ("The World Calendar—A New Calendar for a New World." Pp. 32. World Calendar Association, Inc., 630 Fifth Avenue, New York). On the basis of a 364-day year, the year is divided into four quarters, each of 91 days. The first month of each quarter contains 31 days and each of the others 30 days, and January, April, July and October contain each 31 days. Every year and in consequence every quarter begins on a Sunday, and it is suggested that the national holidays of every country can be arranged to come on Mondays, if the people wish it, thus producing long week-ends. Christmas Day falls on Monday every year, and it is suggested that Easter should be the second Sunday in April, that is, April 8. As a result of fixing Easter for this date, the other movable Christian festivals, Ash Wednesday, Good Friday, Ascension Day, Whitsunday, etc., would occur on the same date every year. Such a stabilization of the hitherto movable festivals would place Advent Sunday on December 3 and Trinity Sunday on June 3—exactly six months apart. The 365th day will be at the end of December and it is recommended that it should be designated as a World Holiday by all countries accepting the new calendar. This World Holiday is an extra Saturday, called the Year-End Day. Leap Year Day is placed at the end of June, in the middle of the year, and it is also an extra Saturday and a World Holiday. The beneficial effects of the reform are explained in connexion with the various phases of life—industry, labour, Government, law, finance, science, etc.; and an appeal is made to the citizens of different countries to lend their support to the scheme.

The Problems of the A-Type Stars

OTTO STRUVE and P. Swings have an article with this title in the August issue of the *Observatory* (No. 809, 64, August, 1942). Morgan pointed out about seven years ago that there is some physical factor other than temperature and surface gravity concerned in the production of the spectra of these stars. The theory of ionization has failed to solve the problem, and the authors are convinced that existing interpretations, which are very unsatisfactory, should be abandoned. They believe that a new solution should be attempted along lines which have been forced on them by the results of their recent work on stellar shells, Wolf-Rayet stars and planetary nebulæ. It is suggestive that certain peculiarities occur in that region of the sequence of the stellar spectra where the Lyman lines and the Lyman continuous absorption cause a large redistribution of the energy in the continuous spectrum. This redistribution has a profound effect on the continuous spectrum of an *A* star, as shown by the curve computed by Pannekoek for a temperature $T_0 = 8{,}480°$, and it must have a marked influence on the ionization as well as on the excitation of those elements the ionization potentials of which lie in the region of 12 volts. Research in recent months has led the authors independently to the conclusion that this physical dilution of radiation—as contrasted with the geometrical dilution observed in shells—plays a very important part in a number of problems, and various instances of this are given. A wide variety of unexplained observations are capable of interpretation along the general lines suggested by the authors, details of which are to be published in the *Astrophysical Journal.* Departures from thermodynamic equilibrium are now being emphasized by recent developments in stellar spectroscopy, in contrast to the long and successful period characterized by the use of thermodynamic equilibrium.

Infra-red Baking

A RECENT article by H. Seymour (*The Electrician*, August 21) surveys the present state of the technique of infra-red baking of industrial finishes. The article makes brief reference to early development and mentions that although first patented some seven years ago, radiant heating received little attention until adopted by the Ford Motor Co. It is emphasized that the rate of temperature rise depends primarily on the difference between the energy gain of the stock by absorption of radiation, and the loss of heat by re-radiation and convection; and that the temperature of the stock and its surroundings should be of the same order of magnitude. Depending on the linear absorption coefficient and absorptivity of the film, baking or heating may occur from the inside outwards, the outside inwards, or uniformly throughout the film.

A description is included of the various types of radiant heating lamps, and of their early development; reflectors and their surfaces; and the present trend of design. Reflector surface fouling by dust and fumes receives special mention, while reference is made to a new type of unit with a sealed lens which obviates cleansing, reduces the fire hazard, and avoids reflector surface damage. An intensity survey is included which discusses the possibilities of obtaining uniform energy intensities over surfaces normal to the lamps. The results of recent research into the infra-red absorption characteristics of various paint pigments ground in similar vehicles are given. The conditions for maximum utilization of electrical energy are examined and it is stated that this obtains when the air temperature is higher than the stock temperature. Vapour removal, performance ratio, maximum heat densities and oven arrangements are discussed, and the view is expressed that future practice will utilize radiant heat lamps augmented by auxiliary heaters.

Soldering Electrical Joints

AN article in the *Electrical Review* of August 28 describes the technique and selection of suitable materials. The process of soldering may be defined as the uniting of metals by means of an alloy melting at a lower temperature than their fusing points, as distinct from welding in a state of fusion. The solder alloys with the surface layers of the parts to be joined and the process is not simply one of adhesion. There are two broad classes of soldering, namely, soft soldering in which tin-lead alloys are mainly used and hard soldering in which alloys of copper-zinc (brazing) or of silver-copper-zinc (silver soldering) are employed. Soft soldering is used very extensively in electrical work and silver soldering to some considerable extent; brazing is rarely used. The electrical conductivity of soft and hard solders is considerably less than that of copper, varying with composition between approximately 9 per cent and 13 per cent for soft solders and 20 per cent and 40 per cent for silver solders.

Some or all of the following points must be considered in the selection of soldering processes for joints in current-carrying conductors. (1) Thorough cleansing and adequate heating, but not overheating. (2) As little solder as possible should be used, to obtain low electrical resistance and high mechanical strength. (3) Solder must not weaken at normal working temperatures. (4) Due to high centrifugal forces encountered in many electrical joints (for example, soldered commutator connexions), solder must be both strong and ductile. (5) Fluxes of a corrosive nature must be avoided, and flux residue easily removable. (6) Solders used for joining copper in the manufacture of cables must be strong and ductile to withstand the subsequent drawing operations; silver solders are generally employed. The article gives tables of solder compositions, properties and characteristics.

Health of the Swedish Army

ACCORDING to the August issue of the *Anglo-Swedish Review*, General Ivar Holmquist, Commander-in-Chief of the Swedish Army, has recently declared that, without going into technical details, he was sure that the Swedish soldier was one of the best in the world. What he lacked was only battle experience, but he was at least partly likely to make up for this by his excellent physique. Moreover, the nerves of the soldiers were in good order, they did not suffer from war weariness, the material was in first-class condition and had not been worn out by war, nor had the élite troops been decimated. Although it was deplorable that so much of the country's labour and resources had to be used for military purposes, the effort was not altogether wasted. For the general health of the nation it was important that the young men of twenty should receive one year's excellent physical training in the open air. During a recent tour of inspection among the mountains of Lapland, he was pleased to see with what vitality and enthusiasm these young men carried out a march of 13 miles in alpine terrain rising from 1,000 to 3,000 feet and then delivered an attack down a mountain slope carrying the heavy equipment of machine-guns and trench mortars which had been conveyed on sledges during the march.

Public Health in Peru

IN a recent article (*Bol. Of. San. Panamericana*, 21, 540; 1942) Dr. Constantino J. Carvallo, the Minister of Public Health, Labour and Social Welfare, gives a description of public health in Peru from December 1939 to July 1941. The chief health problems of this country are malaria, tuberculosis, children's diseases, venereal diseases and other contagious disorders. Health campaigns which have already begun include surveys, health examinations, vaccination, establishment of clinics and dispensaries, early treatment, rural hygiene, drainage of swamps and stamping out foci of infection, port and river sanitation and housing. A department of industrial hygiene was established in August 1940, while nutrition problems are handled by the National Nutrition Administration founded in February 1940.

Zoological Society of London : New Secretary

DR. S. A. NEAVE, C.M.G., O.B.E., director of the Imperial Institute of Entomology, has been elected honorary secretary of the Zoological Society of London to fill the vacancy caused by the resignation of Prof. Julian Huxley. Dr. Neave will hold office until April 1943, when the next annual general meeting will be held. Dr. Neave's work, especially in economic entomology, is well known. He was naturalist to the Geodetic Survey of Northern Rhodesia during 1904–5; entomologist to the Katanga Sleeping Sickness Commission during 1906–8 and entomologist to the Entomological Research Committee (Tropical Africa) during 1909–13. From 1918 until 1933 he was honorary secretary of the Royal Entomological Society and was its president in 1934–35.

Alphonse François Renard (1842—1903)

THE Belgian geologist Alphonse François Renard, who with Murray reported on the rock deposits from the bottom of the sea collected by the "Challenger" expedition, was born at Renaix in East Flanders on September 27, 1842. Educated at Rome for the Church, during 1866–69 he was superintendent at the Collège de la Paix at Namur, and then entered the Jesuit College at the old abbey of Maria Laach in the Eifel. Taking up the study of geology and chemistry, in 1874 he was made professor of those subjects at the College of the Belgian Jesuits at Louvain and a few years later was made a curator of the Royal Natural History Museum at Brussels. Though ordained a priest in 1877, he abandoned his intention of entering the Society of Jesus and separated from Rome, resigned his post at Louvain in 1882 and in 1888 was appointed professor of geology in the University of Ghent, a post he held until his death. In conjunction with Vallée-Poussin (1827–1904) he wrote on the plutonic rocks of Belgium. The Geological Society in 1885 awarded him the Bigsby Medal. He died at Brussels on July 9, 1903.

The Night Sky in October

THE moon is new on October 10d. 04h. 06m. and full on October 24d. 04h. 05m. U.T. The following conjunctions will occur during the month: Oct. 3d. 16h., Jupiter in conjunction with the moon, Jupiter 3° N.; Oct. 27d. 11m., Saturn in conjunction with the moon, Saturn 3° N.; Oct. 31d. 05h., Jupiter in conjunction with the moon, Jupiter 3° N. Occultations of naked-eye stars during the month are as follows, the times referring to Greenwich :

d.	h.	m.			
6	03	44·3	18	Leonis	*R*
26	21	52·3	γ	Tauri	*D*
	23	02·1		Tauri	*R*
27	03	44·7	θ′	Tauri	*D*
	04	24·6		Tauri	*R*
27	04	37·8	75	Tauri	*R*
27	07	51·7	α	Tauri	*D*

On October 11 Mercury is in inferior conjunction and on October 26 will be at an elongation favourable for northern observers, rising about 2h. before the sun. Venus is too close to the sun to be observed during the month. Mars is in superior conjunction on October 6 and is not well placed for observation. Jupiter is favourably placed for observation after midnight, and Saturn, near Aldebaran, rises early in the night, southing about 3h. in the middle of the month.

Announcements

SIR D'ARCY THOMPSON, professor of natural history in the University of St. Andrews, has been elected president of the Royal Scottish Geographical Society, in succession to Lord Rosebery.

THE Lord President of the Council has appointed Sir Lawrence Bragg, Prof. J. E. Lennard-Jones, Dr. A. McCance and Sir Raymond Streat to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research from October 1. Dr. G. M. B. Dobson and Mr. S. K. Thornley will retire from the Council on completion of their terms of office on September 30.

By an Order of the Committee of Privy Council, made after consultation with the Medical Research Council and with the president of the Royal Society, Prof. D. Keilin, Quick Professor of Biology in the University of Cambridge, and Sir Henry H. Dale, retiring director of the National Institute for Medical Research, have been appointed to be members of the Medical Research Council in succession to Prof. L. J. Witts and Prof. C. R. Harington, who retire in rotation on September 30. By the same Order, Sir Charles Glen MacAndrew, M.P., has been appointed to be a member of the Council in succession to the Right Hon. James Gray Stuart, M.P., also from October 1.

DR. HARRISON E. HOWE, editor of the *Journal of the American Chemical Society, Industrial and Engineering Chemistry*, and a trustee of Science Service, has been awarded the Chemical Industry Medal for 1942 by the American Society of Chemical Industry.

MR. F. H. WYNNE retired from the post of H.M. chief inspector of mines on September 20, on reaching the age limit. He is succeeded by Mr. J. R. Felton, who has been the deputy chief inspector since the end of 1937.

DR. FÉLIX AGUILAR, director of the National Observatory, La Plata, Argentina, writes that one of his colleagues, Mr. Gualberto M. Iannini, has undertaken to compute a definite orbit of Comet Whipple, 1942 *a*. He would be very grateful for data, especially from observatories in the northern hemisphere.

THE opening meeting of the new session of the Iron and Steel Institute will be held on October 13, at 2.30 p.m., in the lecture theatre of the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2, when the president, Mr. W. M. Selvey, will present a short address. This will be followed by the presentation of the Melchett Medal for 1942 to Dr. Arno Carl Fieldner, chief of Fuels and Explosives Services, United States Bureau of Mines. As Dr. Fieldner cannot be present, the medal will be accepted on his behalf by the United States Embassy. The Melchett Lecture, entitled "The Analysis and Testing of Coal in Relation to its Properties and Utilization", will, in Dr. Fieldner's absence, be delivered in the form of a talking film of himself reading it, which will be reproduced in the lecture theatre.

Functions of the Research Associations

SIR LAWRENCE BRAGG's valuable and thought-provoking address at the Royal Institution on March 26 (NATURE, July 18, p. 75), under the title "Physicists during and after the War", readily recognizes the value and status of industrial research. This will be welcomed by many who are connected with industry, and who often know more of what is going on in the universities than the universities do of what is being done in industry. Unfortunately, there is no doubt justification for his assumption that there does exist, among many university professors, a feeling that industrial research is of an inferior kind. This is mainly through lack of knowledge of the scope and kind of work now covered by the expression 'industrial research'.

Reference is made by Sir Lawrence to the ardent reforms that are in the air, and he discusses among other things the merits of one of the proposals—that new institutions for pure research divorced from teaching should be founded. Is the field not already covered ? We have first the celebrated schools of university research, where pure research is carried on usually without any thought of practical application. On the other hand, we have the research laboratories of industrial firms where research is mainly applied, except in the bigger ones (for example, some of those connected with the electrical, metallurgical, textile and chemical industries) which also carry out fundamental work. The missing gap between these two was filled by the inauguration, twenty-four years ago, of the Research Associations. One of the special features of a Research Association is that it is the only organization in Great Britain having a bird's eye view of an industry's problems, and that can therefore formulate its research programme in the best interests of the industry as a whole. I do not see that any advantage would be gained to the State by the formation of a fourth class of research institution of the type to which Sir Lawrence refers, and of the value of which I gather he himself is sceptical. One example of this kind is the suggestion made by Prof. J. D. Bernal in his book "The Social Function of Science" for the foundation of a comprehensive "Fibre Institute". Would such an institution be in a position to do better work than is already done ? Without mentioning the mass of research work on fibres carried out (and published) by the textile Research Associations, could the fine work done, for example, by Prof. J. B. Speakman and by Dr. W. T. Astbury at the University of Leeds, be easily improved upon ? In so far as such work suffers from lack of equipment, this could be met by giving larger grants for this purpose to existing institutions and not by forming new ones.

Sir Lawrence thinks that the general conditions under which Research Associations work militate against the production of really fundamental ideas. He compares the Research Associations unfavourably in this respect with the universities on one hand and the industrial laboratories on the other. I do not think this is really so ; it may be true that the Research Associations as a whole have not devoted as much of their resources to fundamental research as would be desirable, but this is not in my opinion due at all to their organization and the intermediate position they hold between the universities and industry. I rather take the opposite view that this position gives them a unique opportunity to carry out the highest class of fundamental creative work, with contacts with the universities and at the same time a comprehensive mental picture of the central problems of their own industry, while completely free from the rush and bustle associated with industrial production. I suggest that if any of the Research Associations have failed to produce a fair quota of new fundamental scientific knowledge, the explanation is to be sought in lack of resources and not in their organization or position in the scheme of things. It is of extreme importance that a Research Association should maintain a proper balance between the accumulation of fresh knowledge and development of new ideas on one hand, and their application to their own industry on the other. Fundamental scientific work must go on simultaneously with the application of knowledge previously gained. Without big resources it is very difficult, if not impossible, to maintain this condition.

There are still a great number of university teachers who do not realize that research in pure science is not confined to the universities, but no one really familiar with the work of the Research Associations (and possibly, in particular, the larger ones) would, I think, deny that a great deal of purely scientific research is carried out with no other immediate aim than the accumulation of fresh knowledge and with no limitation of the freedom of the individual worker through too much 'direction' from above. Indeed, in one sense I would say the young graduate, after joining a Research Association, is more free than the raw graduate in a university laboratory, who commonly obtains his research training within the limits of his professor's own specialized (and sometimes narrow) field—a system which has led in physics to something akin to inbreeding, and to the scarcity of young physicists who have a first-class general knowledge of 'properties of matter' physics.

Sir Lawrence emphasizes the idea of a Research Association as being "ideally a permanent laboratory with special equipment, but with a changing population, not as being a permanent body of men", and goes on later to refer to the opposite side of the picture "only too commonly seen", of research being "directed" by a Committee, which is too impersonal a body to direct research, and the members of which "are generally too busy and important to give the necessary time and attention to detail".

Too much emphasis can be placed on the idea of a changing population, though I agree that augmentation from time to time of the staff from outside by fresh, unprejudiced minds is highly desirable. But such changes should generally, though not necessarily always, be among the younger research staff, rather than the more senior men. It is not always realized that nearly all the Research Associations are unique in that they serve the older industries which were flourishing trades before industrial research had ever been heard of. It follows from this that one of the first essentials to the success of a Research Association is the complete confidence of the technical men in the industry in the Association's most senior staff, and this can only come about—in the larger industries in any event—through much personal contact and recognition by the industrialists of the intimate knowledge these senior men have acquired through close study of the industry over a great many years. Constant changes among senior men would do a Research Association a great deal of harm.

As regards research being run by committees, while it is true that research committees do exist, and that they approve the research programme, I have never heard of a case where fundamental scientific work has been hindered through this system. From the very constitution of these committees, the suggestions which come from them are, so far as my knowledge goes, nearly always concerned with *applications* of knowledge the Association has already gained—a field in which they are eminently qualified to make suggestions, often valuable ones.

Sir Lawrence's suggestion that there should be more contacts between research workers in the universities and those in industry has great possibilities. I would therefore extend a cordial invitation to any professors who feel an urge to write about Research Associations, but who may possibly feel that before doing so they would like to know more about them, to visit the Shirley Institute, and form their own opinion of the purely scientific researches carried on there normally in peace-time.

F. C. Toy.

British Cotton Industry Research Association,
Shirley Institute,
Didsbury,
Manchester.
Sept. 1.

I am too conscious of the lack of contact which has often existed between the university and the industrial researcher not to sympathize with much of what Dr. Toy says on the functions of the Research Associations, and one cannot resent the mild sting which he has permitted himself to add to its tail!

He mentions two difficulties with which the Research Associations have to contend: lack of resources and the fact that for the most part they serve the older industries. As regards the first, it has often been pointed out what a small fraction of our national income we devote to research, as compared with other industrialized countries. As regards the second point, the older industries have a wealth of technical experience, and it is an arduous task for the man of science, using his fundamental knowledge, to surpass the skill and lore acquired by long practice.

Dr. Toy rightly stresses the undoubted fact that in spite of these handicaps much fine original work is done in the Research Associations. Yet on re-reading my own article, I do not feel that Dr. Toy's views are in conflict with its main points, and hope that readers of Nature will come to the same conclusion. In discussing physics in industry, the last thing I had in mind was a criticism of any particular body of men. I expressed a conviction, and reaffirm it, that we have not yet discovered the best way of applying our great resources of native scientific ability to the strengthening of our industrial position.

W. L. Bragg.

Encouragement of Research in Industry

The point made by Sir Lawrence Bragg[1], and again by Mr. Benham[2], concerning the need for freedom for scientific work from other interferences, cannot be too highly stressed.

The fact that scientific workers are generally blessed with a good fund of 'common sense' often results in many jobs in industrial establishments being passed over to them for attention, jobs which more properly should be dealt with by other departments of the organization. Their greater technical knowledge of the jobs means that they are better done—but only at the cost of interruption of their proper research or development work. Too often also they are called upon to put right the mistakes of other sections of the business—mistakes which should not have occurred if adequately trained staff had been employed in those sections. Financial considerations, however, doubtless influence this in many instances.

Reluctance of the production staffs to make use of the developments of the research workers is not confined to the senior supervising staff. In many cases it extends down to the foremen, to the charge hands and to the workers themselves. It can only be overcome by the friendliest co-operation between both sections. This co-operation is seldom easy to secure, because they generally talk in different 'languages', and think in different terms.

A good liaison engineer (but one who has no particular flair for research), between the development or research section and the production departments, is probably the best solution. If he has had a little post-graduate research training he will appreciate the finer points and needs of the scientific aspects of the problem; while if he is a good engineer he will be able to translate these into the necessary applications in the manufacturing departments and see that their difficulties—and they will always have difficulties with any new process—are given sympathetic attention.

The suggestion made by Mr. Benham that more use should be made of shorthand typists in research laboratories is a good one, and I should like to endorse it heartily. Provided that they are reasonably intelligent and can be trained to present the data in a proper form and can take some useful action regarding other matters on which they may be given notes during the progress of some investigation, they can be a great asset. Good ones for this type of work are not easy to find. I would suggest further that if mechanical calculating aids are available—and at the very least an adding machine should be 'on tap' in every laboratory—they should be taught to operate them so that their sphere of utility to the research worker can be much increased. In many cases, however, it does not prove easy to convince the management of needs such as these.

This, again, is another argument in favour of Sir Lawrence Bragg's plea that all laboratories should be given authority for certain expenditure entirely without reference to any outside control. The researchers will then quickly get the equipment most useful to them; without the wearisome arguments necessary to justify it to others—who cannot appreciate the real needs of the moment. Only too often is work spoiled or improperly completed on this account.

Finally, as Mr. Benham says, give the researchers more responsibility. If expenditure on the research is justified at all, it is all the more justifiable that the researchers should be given the responsibility and authority to see that their work is properly applied in the production departments. They must rank equal with the production managers and not be entirely subordinate to them.

Homology of the Campaniform Organs on the Wing of *Drosophila melanogaster*

In the normal wing of Drosophila the campaniform sensilla have been noted by McEwen[1], and have been shortly described by Hertweck[2] who termed them "*kuppelformige Organe*". They are arranged in well-defined positions which include several large groups at the base of the radial vein; single organs are found more distally on the first and third longitudinal veins and the anterior cross-vein (Fig. 1*a*). These organs show considerable variation in size, those at the base of the wing being the smallest. When viewed from the side a large sensillum from the distal part of the radius is seen to consist of a cuticular dome set in a socket-like elevation of the cuticle (Fig. 2*b*). Smaller sensilla from the base of the wing have a similar, though smaller, dome, but the socket-like part of the complex is much less conspicuous and seems to be represented by the rim of a shallow saucer-like depression in which the dome is inserted. All the organs are circular or nearly so. In section their structure is seen to be typical of this type of sensillum (Fig. 3): each is innervated by a single sense cell from which arises a 'sense fibre' which is inserted on the inner side of the dome; the sense fibre with the exception of the tip adjacent to the dome stains deeply with hæmatoxylin, a property which is shared by the inner lining of the dome (the "*Polstermasse*" of German authors).

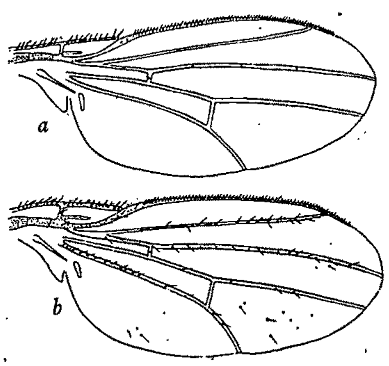

Fig. 1.

a, Diagram of the dorsal surface of a normal wing showing the positions of bristles and campaniform sensilla—the latter are indicated by dots; *b*, the same for a 'hairy' wing. In both, certain ventrally placed sensilla and a large group of sensilla on the extreme base of the wing are omitted.

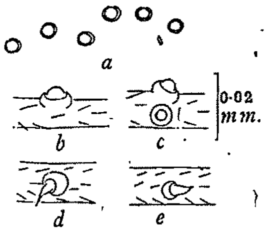

Fig. 2.

a, Surface view of part of a group of small campaniform organs on the base of the radius; *b*, side view of a normal large campaniform organ from the distal end of the radius; *c*, a reduplicated organ: *d–e*, structures intermediate between campaniform sensilla and bristles; *c–e* are from a 'hairy' wing.

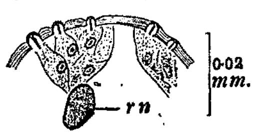

Fig. 3.

Transverse section through a group of small campaniform organs on the base of the radius in 'hairy wing'; *rn*, radial nerve.

The non-allelomorphic genes 'hairy' (*h*,3-26.5) and 'hairy wing' (*Hw*,1-0·0), as is well known, control the production of extra bristles on the thorax and wing of Drosophila; in addition, they also exert a very considerable effect—and in general the effects of both genes are very similar—on the wing campaniform organs. This does not appear to have been previously recorded. In these mutants the number of campaniform organs on the wing is greatly increased, for example, a typical 'hairy' wing may carry more than 150 organs compared with the normal complement of some 85. Most of the extra organs are found on or near the base of the radius, although a variable number occur more distally on the other veins or scattered in irregular groups on the intervein membrane (Fig. 1*b*). The most interesting effect, however, concerns the large distal campaniform sensilla, many of which are transitional in form between normal organs and typical bristles (Fig. 2 *d–e*); in these the socket-like element remains unaffected but the dome is produced into a small spinous projection. All intermediate stages between normal campaniform organs and fully formed bristles can usually be found on a single wing.

The derivation of the various types of insect sensilla from a central type such as the trichoid sensillum or bristle has sometimes been suggested. In the case of the campaniform sensilla Snodgrass[3] suggests that the bristle may have been lost but the socket retained. From the evidence outlined above it would appear that both elements of the apparatus are retained and that the dome of the campaniform organ is the homologue of the bristle. Unfortunately, the cells which give rise to the campaniform organs are not present in the adult, and, owing to their small size, it has not yet been possible to identify them with certainty in the developing wing. It is known[4], however, that in Drosophila, as in other insects, normal bristles are produced by two cells, one of which, the trichogen, secretes the bristle proper, while the other, the tormogen, gives rise to the socket. It is not improbable that two cells are also concerned in the formation of a campaniform sensillum and that one secretes the dome and the other the raised rim or socket-like part of the complex. When these organs are relatively small as at the base of the wing in Drosophila it is possible that the homologue of the tormogen fuses with the general cuticle or produces at most a shallow rim, rather than secreting a discrete socket-like structure such as is found in the more distal organs. The immediate cause of the normally strictly alternative type of secretion—campaniform dome or bristle—is not clear, but the obvious difference in the amount of cuticular material present in these elements is likely to be reflected in the respective sizes of the formative cells concerned.

These same organs have been wrongly referred to by me as "chordotonal organs"[5]. Observations made on the sensilla and conclusions drawn remain, however, unaffected.

Feeding of the Common Toad

THE accompanying photographs of the feeding of the common toad (*Bufo vulgaris*, Laurenti) supply, I believe, for the first time an accurate description of the tongue movement in an Anuran. The movement in the frog is similar, but I have not so far obtained such satisfactory photographs of it. Most modern text-books assume that protrusion of the tongue is accomplished by lymph pressure. The evidence for that theory is slight[1], and these photographs argue against it and in favour of a muscular mechanism, because (1) the time of protrusion is shown to be so short (sometimes less than 1/20 sec.); (2) the tongue and floor of the mouth show no signs of inflation; (3) there is a distinct constriction at the base of the tongue when viewed from above in the fully extended position (see Fig. 2). These features, and others, suggest a muscular mechanism similar to that proposed by Gaupp[2] on anatomical grounds; with the probability that purely intrinsic muscles play a larger part than he thinks, especially in the unrolling of the tongue and in the first part of retraction. It is still possible that lymph pressure may play a subsidiary part.

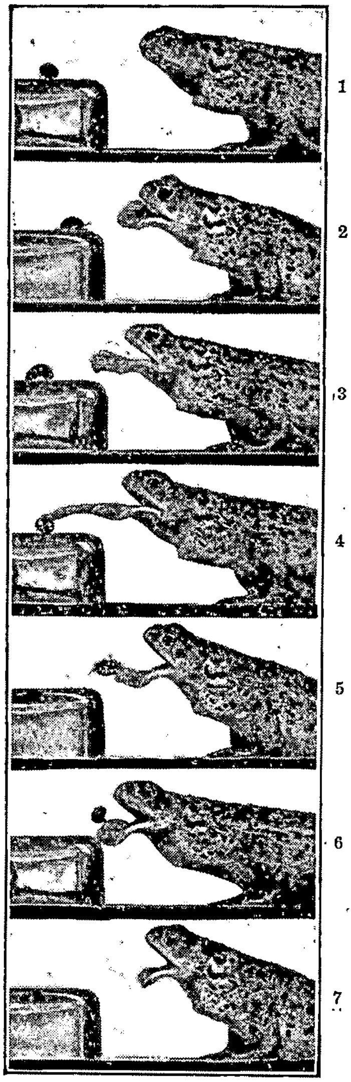

Fig. 1.

TOAD FEEDING; FROM SIDE. RECONSTRUCTED SERIES; NOS. 1, 4, 6 AND NOS. 2, 5, 7 ARE CONSECUTIVE FRAMES OF TWO SHOTS. FIG. 2 WAS TAKEN SIMULTANEOUSLY TO THE LAST OF THESE SHOTS. THE PREY IN ALL CASES IS A WOODLOUSE.

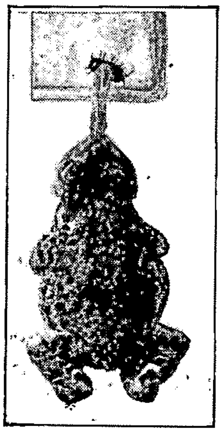

Fig. 2.

TOAD FEEDING: FROM ABOVE. TONGUE FULLY EXTENDED.

The entire movement occupies little more than 1/10 sec., divided nearly equally between protraction and retraction. The dorsal surface (at rest) is here only elongated to about eight sevenths of its length at rest, though other photographs show that it can be elongated slightly more than that. In its other dimensions there is very little change, except that it is slightly narrower when seen from above. The length of the protruded tongue in this female, which measures 3 in., is 8/10 in., from the tip of the lower jaw. Fig. 1, No. 5, shows from the legs of the prey that the tip of the tongue is rotated through 180° at the beginning of retraction.

Response to Colour in Birds

APART from some experiments by Marples[1], little work appears to have been done on the colour awareness of birds in their wild state. By colour awareness is meant the ability to detect and react to light of widely differing wave-lengths. The possibility that such recognition may, in birds, involve merely the detection of different intensities of a single shade has not been overlooked, but is contra-indicated by the experiments described here. These experiments have been carried out by utilizing the instinct of nest-sanitation whereby most birds, and especially those of the Passerine order, keep their nests free from contamination by the excrement of the young. This instinct has been shown by Smith[2] to be of the same order of strength as that to feed the young, and the provision at the nest of artificial fæces of various colours gave a ready means of testing the response to colour in certain species. These artificial fæces were made from 'Plasticine' moulded into the shape and size of a fæcal sac, and spectroscopic analysis of the samples employed gave the data shown in Table 1.

TABLE 1.

Colour	Brightness factor	Hue wave-length ($\mu\mu$.)	Saturation
White	0·586	578	0·156
Yellow	0·362	578	0·448
Green	0·222	549	0·348
Red	0·134	492*C*	0·228
Purple	0·116	566*C*	0·006

(*C* = complementary colour.)

The colours are thus far from pure, but this was to be expected from a substance like pigmented 'Plasticine'.

The artificial fæces were placed on the rim of the nest, in a similar position to that used by the nestlings. Their arrangement was quite random, and was changed for each trial. Observation of the order of removal of the artificial fæces was made from a 'hide' in close proximity to the nest. If birds were colour-blind, the order of removal would be in the order of decreasing brightness factor, since the brightness factor is defined as that attribute of a colour in respect of which it can be classed as equivalent to some member of a series of greys ranging between black and white. The results of trials at nests of the meadow pipit (*Anthus pratensis*) and the yellow wagtail (*Motacilla flava flavissima*) are given in Table 2, and show no correlation with the brightness factor.

TABLE 2. ORDER OF REMOVAL OF DIFFERENTLY COLOURED ARTIFICIAL FÆCES FROM NESTS. ROMAN FIGURES BY ♂ BIRD; ITALICS BY ♀.

Species	Trial	Red	Yellow	Green	Purple	White
Meadow Pipit	*a*	4	*3*	1	Ignored	*2*
	b	*4*	*3*	1	5	*2*
	c	*5*	*3*	2	4	*1*
	d	*4*	3	1	Ignored	*2*
	e	*4*	3	*1*	*5*	*2*
Yellow Wagtail	*a*	5	1	4	3	*2*
	b	5	1	4	3	2
	c	4	1	5	2	*3*
	d	5	2	4	1	*3*

Fig. 1 shows the female meadow pipit removing, during trial *c*, the yellow (*Y*), while the red (*R*) and purple (*P*) fæces remain on the rim of the nest. Fig. 2 shows the male yellow wagtail removing, in trial *d*, the yellow (*Y*), while white (*W*), green (*G*) and red (*R*) remain.

It is evident that, to the meadow pipit, green must appear as a very bright colour, since in four out of five trials it was taken as first choice. Yellow occupies an intermediate position and red and purple are last choices; purple particularly failing to attract attention. With the yellow wagtail, on the other hand, the order of choice was strikingly different. With this pair of birds, the female refused all the artificial fæces except the white ones, but the male readily removed them all. His first choice was yellow in three out of four trials, after which he took purple or white. In trial *d* purple was first choice. Green, on the other hand, was the penultimate, and red the last choice, three times in four. These results are in striking contrast to those obtained with the meadow pipit, especially in relation to the significance of yellow and purple. Pipits and wagtails are both Motacillidæ, but while the former tend to have dull brown plumages, the wagtails are often brightly coloured with yellow and blue frequently predominating, and although much more experimentation is needed before any conclusive correlation can be made between the colour awareness of birds and their plumage colours, the very obvious pointer to such a correlation cannot be ignored, especially when it is remembered that the yellow wagtail is a sub-species of the basic blue-headed form, *Motacilla flava flava*.

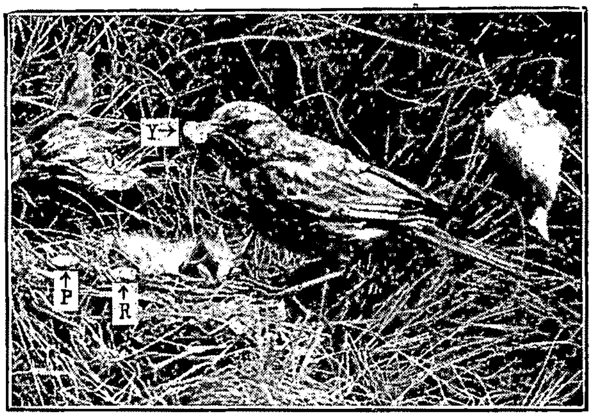

Fig. 1.

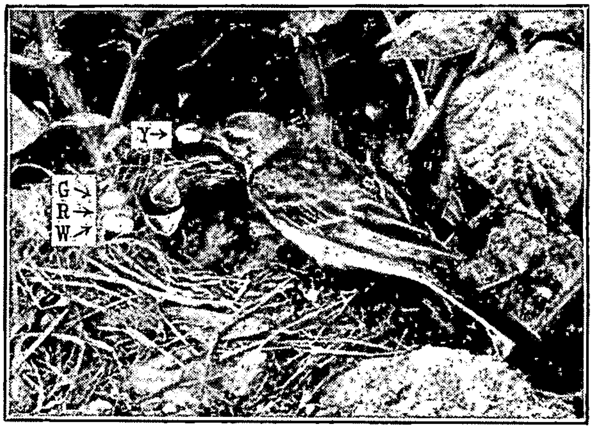

Fig. 2.

The use made of the brighter-coloured parts of their plumage by male birds in nuptial and aggressive display is well known, and in this connexion the work of Lack[3] on the robin (*Erithacus rubecula melophilus*) shows that for this bird, in contradistinction to the two species above, red is a highly significant colour.

These, and other related experiments, will receive detailed treatment in another place.

A False-Ring Pattern in Larch

DURING the course of the Timber Felling Survey organized by Prof. H. G. Champion, and undertaken for the Forestry Commission by university research parties during the summers of 1940 and 1941, it fell to my lot, as plant pathology member of the Bristol Party, to examine and make counts of the annual rings on felled timber, chiefly European larch.

Such counts, made in the field, proved at first very unreliable owing to the difficulty of determining false, partial or missing rings, and of interpreting the outer rings of suppressed trees. The practice was therefore adopted of taking back from each plot at least one complete cross-section of a butt which was planed and examined in the laboratory. This resulted in the discovery that in nearly all the butts of European larch examined, taken from all parts of the area covered by the Bristol Party, there was a general and recognizable pattern formed by the false rings.

Fig. 1*a* records the percentage of reliably dated annual rings from 1900 to 1940 which showed one or more false rings, including as such everything from slight traces to complete additional rings. It is based upon examination of 105 butts of European larch 25–60 years old. If the false rings on single butts are plotted to the same scale, as shown in Fig. 1*b*, each of the plans so formed will usually fit the master plan best in one position, that corresponding to the correct dating. Exceptions are found in trees with completely unchecked growth, which may have few or no false rings, old trees in which the outer part covered by the established pattern is suppressed, and a few 'oversensitive' butts in which there are so many false rings that the pattern is swamped. In general, the number of false rings appears to vary inversely with the soil depth.

Not only the occurrence of the false rings, but also their number, appearance, and position in any given year's growth, are all of value, and there is now no difficulty in fitting into the pattern any 30- to 50-year-old butt from the south-west region which shows a fair number of false rings. Older trees also show characteristic false rings during their period of maximum ring-width, and the pattern has been tentatively extended back to 1860, but is unreliable owing to the small number of trees examined.

The area from which butts were examined extends very roughly fifty miles round Bristol. The five false-ring plans shown in Fig. 1*b* are from single butts taken from the following localities:

(A) White Hill, near Monmouth.
(B) Pump Ground, Stanway Estate, north-east of Winchcomb, Glos.
(C) Old Hill, near Wraxall, 7 m. west of Bristol.
(D) Huish Cleeve, near Wiveliscombe, Somerset.
(E) Grange Hill Farm, near Basingstoke, Hants. (from a section kindly sent to me by a member of the Oxford Party).

The pattern varies in characteristic fashion from one district to another, but the similarities throughout the area remain more striking than the differences.

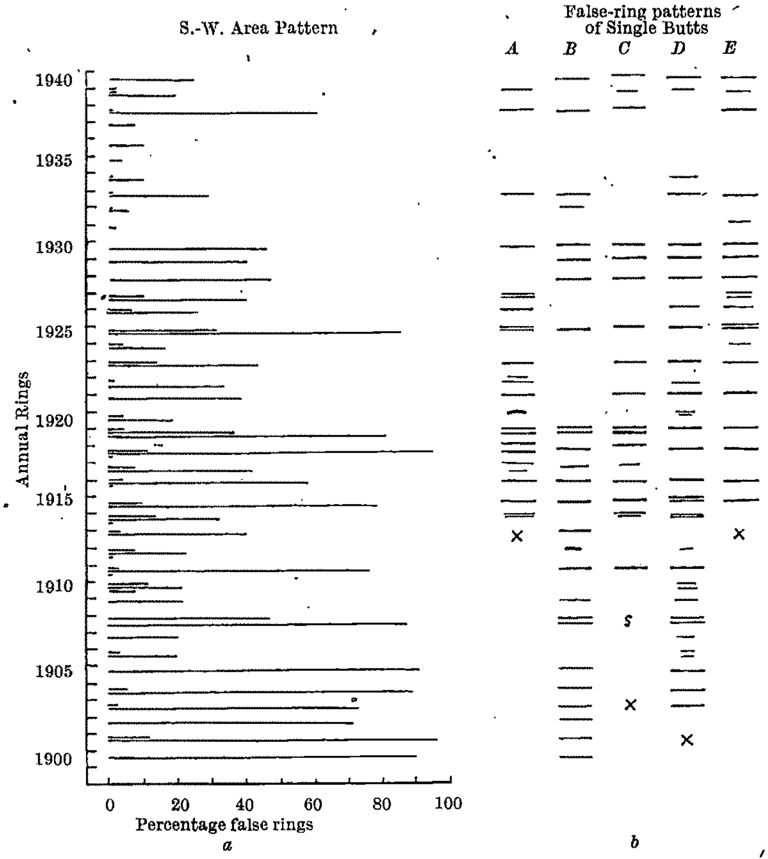
A majority of the butts examined came from the northern part of the area: 26 from the Wye Valley and Dean area, 36 from the Stanway Estate on the Cotswold plateau, 12 m. north-east of Cheltenham, 23 from a few miles west of Bristol, and the remaining 20 from widely scattered places in Somerset, west Wilts, and a few from as far east as Basingstoke and King's Somborne, Hants. The pattern shown in Fig. 1*a* has therefore a strong bias in favour of the local patterns in the northern part of the area. Nevertheless, the chief elements are present throughout the area and it will be of interest to see how widely they extend beyond it.

The most frequent and conspicuous false ring is found in 1918, about the centre of the year's growth; others are in 1938, 1925 (often double), 1919 (often double), 1915 (early central), 1911, 1908 (wide double), and the years 1900–1905, in which, however, the percentages are less reliable owing to the smaller number of records.

Once the probability of occurrence, and the typical position and appearance of the false rings in each year's growth had become known, the pattern was found to be of great practical use in the field. For example:

(1) It provided a check on the ring count, often revealing missing or inconspicuous annual rings which had not been seen or had been misinterpreted.

(2) It gave the ages of trees with suppressed outer rings, and of sections below the felling cuts which did not reach the outside.



×, first year of growth; *s*, annual ring suppressed.

(3) It enabled the outer ring on fairly recently cut timber or stumps to be dated with certainty, and also gave the dating of rabbit scars and other injuries.

(4) Where enough records had been taken to establish a local pattern it enabled unlabelled sections of butts to be referred to their correct sites.

Nineteen butts of Japanese larch show the same general pattern, with a few differences in emphasis; for example, the 1916 false ring is more frequent than the 1915. Other conifers show the 1918 ring, but the false rings, especially in spruce, are less distinct than in larch, and enough material for the formation of a pattern has not been studied.

It is to be hoped that comparison of the pattern with meteorological records will give some information on the effect of climate on the growth of wood and the formation of additional rings. The relationship, however, is unlikely to be simple. Attempts to establish a pattern for annual ring-widths, on the lines originated by Douglass and co-workers in the southern United States, failed completely even with trees on the same site. This was not surprising, as moisture can rarely be a limiting factor in the south-west district of England. Certain annual rings, however, notably those for the drought years 1911 and 1921, are often recognizable, apart from false rings, by their relative narrowness, and the firm, narrow outline of the autumn wood. In a damp, variable climate, it is the composite picture presented by the balance and distribution of the large- and small-celled elements in the wood of each successive year's growth, which makes a perceptible pattern worthy of further study.

Once the general climatic pattern is firmly established, the local variations from it will give useful information about soil conditions and the rooting system, and defoliation due to exposure, insect attack, or other local factors. It can scarcely be over-emphasized that the whole history of a tree's growth in relation to its environment is recorded in its wood, and that it needs only the separation of the general from the special elements in that record to make it intelligible.

The So-called 'Granite Axial Core' of the Himalaya

From time to time there appears in various contexts reference to the predominant mass of granitic rock which, it is claimed or supposed, forms the vast bulk of the Great Himalayan Range, and particularly of its highest peaks. In his presidential address to the twenty-ninth Indian Science Congress, 1942, entitled "The Making of India", Mr. D. N. Wadia said: "The sublime snow-capped peaks of the Himalaya from Mount Everest to Nanga Parbat, all are built of this axial granite core", etc. Now specifically, neither Everest nor Nanga Parbat is composed of granite, although veins of granite-pegmatite or -aplite are fortuitously to be found within their essentially sedimentary constitution, which in both cases is made up of slate, quartzite or siltstone, limestone and schist of varying kind.

The time-honoured, but mistaken, view that the main Himalayan axis is thus composed of granite, or intrusive gneiss, is largely due to the early work of General C. A. McMahon, and other investigators, who did not penetrate far into the inner recesses of the main range, and moreover were mostly concerned with its north-western end. Exploratory expeditions of recent years both in the Central and in the Eastern Himalaya have, however, revealed that granite is nothing like so ubiquitous as has been supposed. In the Central Himalaya of Garhwal and Kumaon, in the region dominated by the great peak Nanda Devi, 25,645 ft., and also extending into Nepalese territory, altered sedimentary rocks such as slates, quartzites or siltstones, with crystalline limestone, compose the greater number of the high peaks which have so far been examined in the main range. The same is the case in the Eastern Himalaya, from the neighbourhood of Gosainthan, the great summit on the northern border of Nepal, through Mount Everest and its satellites, and all along the Sikkim- and Bhutan-Tibetan frontier: we find slates, siltstones and limestone—shore facies of the ancient Tethys Sea—constituting the succession out of which the high peaks have been carved. Para-gneisses and -schists are to be found deeply in the lower parts of many of these mountains, but undoubted ortho-gneiss or granite is restricted to the base of the range in certain districts, with granite veins extending upwards in some areas into the sedimentary series.

I may add that this note has been prompted by Mr. Wadia himself, with whom I recently discussed the matter in India, and its intention is to bring before a wider scientific public than geologists alone what has been one of the misconceived ideas of the nature of the Himalaya. Further details of this matter will, it is hoped, shortly be published elsewhere when military duties permit. The recent disastrous loss at sea of field-notes and partially completed papers relative to a large part of my work during three expeditions in the Himalaya will, however, quite preclude anything like a satisfactory rewriting of the vanished papers on Structure, Glaciology, etc.

The Slide Rule Cursor

It is convenient to be able to check quickly whether the line of a slide rule cursor is accurately at right angles to the scale. We can test the correspondence of a number and its square, but if "log log" scales are available it is preferable to use them as, being further apart, the test is more sensitive.

I have found that 1·55 and 80·0 are almost exactly opposite each other and may be used for the test. The error, being 0·013 mm. in a 10-inch scale, is negligible.

Commission of Forestry Research in Africa

Action which, it is hoped, may give rise to a notable advance in the application of the principles of scientific forestry to the practical affairs of the African continent has recently been taken. I write as Editor of the *Journal of the Royal African Society*, which has on several occasions in recent years reflected the strong interest of that Society in the problem of deforestation and soil erosion in Africa by publishing studies of it—notable among them having been contributions by Prof. E. P. Stebbing.

It occurred last year to Prof. Stebbing that the presence in Great Britain of the Belgians and the Free French, controlling between them territories which, with those controlled by Great Britain, form a belt across the whole of Central Africa, offered a unique opportunity for international study of this problem as a whole, which might pave the way in due course to concerted international action.

The Royal African Society was glad to use its good offices to this end, and, the Belgian Colonial Minister and the Free French National Commissioner for Colonies and the Netherlands Minister for Colonies giving their cordial support, an unofficial International Commission of Research, set up to study deforestation and erosion in tropical countries, came into being under the auspices of the Royal African Society, with membership as follows: Prof. E. P. Stebbing (*chairman*); Governor-General Richard Brunot, governor of Mauritania and Chad; Count P.

de Briey, territorial administrator and assistant provincial commissioner, Belgian Congo; L. Borremans, agricultural adviser, Belgian Embassy in London; A. Muhlenfeld, head of the Department for West Indian Affairs, Netherlands Ministry for the Colonies; Sir William Hunt, formerly lieutenant-governor, Southern Provinces of Nigeria.

This Commission of Research held in all eight meetings, the first on January 2 and the final one on April 10. The verbal discussions were supplemented by valuable notes contributed by the members and others on the various aspects of the questions involved.

The final session was devoted to the adoption of a series of resolutions embodying the Commission's recommendations as to the measures necessary to deal with the problems discussed, these problems having been considered under five main heads as follows:

1. The native custom of shifting cultivation.
2. Bush fires, and the native custom of burning the bush.
3. Grazing.
4. Soil erosion, and reservation of forests.
5. Regeneration of poor or exhausted soils.

On each of these problems the Commission put forward its analysis of the position and its practical proposals for measures to cope with that position.

The proceedings and findings of this Research Commission are being circulated by the Royal African Society to the Governments mentioned and to the neighbouring and other Governments concerned with Africa, in the hope that agreed principles, both of doctrine and of practice, may be regarded as having emerged from the Commission's deliberations, and that this may lead to a new concerted effort to rid Africa, and other tropical countries, of a scourge which, unless dealt with, threatens the very habitability by mankind of large portions of the earth's surface.

Paracelsus and "Basil Valentine"

To honour the memory of Paracelsus, who died four hundred years ago, the Institute of the History of Medicine at the Johns Hopkins University has issued four of his treatises in English translation. In a review of this volume in NATURE (May 9, 1942, p. 510) the statement occurs that Paracelsus "borrowed much, without acknowledgement, from Basil Valentine". To many of us who have formed a definite picture of Paracelsus's character, plagiarism would seem to be the last fault of which he might be rightly accused, and as this imputation (which has been frequently made since the seventeenth century) nullifies to a certain extent the purpose of the memorial volume, it might be permitted to ask whether this slur upon the character of the great man is well founded.

More than fifty years after Paracelsus's death, treatises somewhat similar to his began to appear which purported to be based on the manuscripts of a nebulous personality called Basil Valentine, who was supposed to have lived in the fifteenth century. The tremendous reading of the famous German historiographer of chemistry, H. Kopp, has failed to detect in the richest libraries any trace of such manuscripts or any contemporary reference to the man, and nothing has come to light since. On the contrary, many of the arguments Kopp uttered tentatively to show that the treatises of the so-called Basil Valentine had been written after Paracelsus were strengthened and enlarged by recent studies; of special importance was the discovery, in 1925, by F. Fritz of a book forming clearly a link between Paracelsus and "Basil Valentine".

To assume that Paracelsus was in possession of copies of "Basil Valentine's" writings, that he (who so much despised literary tradition and based everything on his own personal experience and philosophy) used them secretly for gaining credit without a single one of his many embittered enemies discovering and exposing this fraud, and that these manuscripts then vanished completely with the exception of the copies which about 1600 were put into print and then disappeared too—that does not seem a plausible hypothesis. The boot is evidently on the other leg: those of "Basil Valentine's" works which show similarities with Paracelsus's ideas and discoveries were rather composed by a man living in the later part of the sixteenth (and not in the fifteenth) century, who was familiar with the writings of Paracelsus but anxious not to disclose his indebtedness to this inspiring reformer. The pretence of high antiquity, the only argument in favour of the alternative hypothesis, is so common in alchemistic literature that one can scarcely give it any weight in face of such strong evidence to the contrary.

We have no reason to doubt that throughout his life Paracelsus was faithful to the proud maxim he inscribed to two of his portraits: "*Alterius non sit qui suus esse potest.*"

F. A. PANETH.

University,
Durham.

I AM grateful to Prof. Paneth for pointing out a very misleading—if not entirely false—statement. The Paracelsus question is so obscure, and still so controversial, that it was only on re-reading Dr. Bayon's article in the *Proceedings of the Royal Society of Medicine* of November, 1941, that I realized how strongly the opinion of specialists has turned against the "Basil Valentine" hypothesis. It would have been better to have said: "Some have thought that Paracelsus borrowed . . ."; better still to have said nothing at all about Basil Valentine. For, in the days before universal printing and stringent copyright, to borrow was no sin. The habit was common, and did not seriously reflect upon the borrower's honesty, particularly in a work not specially intended for publication, unless originality was claimed or the amount borrowed extensive.

Furthermore, I was concerned, not with an involved and obscure point of literary controversy, but with the value of Paracelsus's doctrines. A little about these would have been more to the point than a reference to the "Valentine" controversy. I hold that Paracelsus did more for science and philosophy than is generally allowed; far more indeed than Dr. Bayon, for example, would put to his credit. It is true that his work was wild, erratic and mixed with fancy and superstition; in other words, he was not a strictly scientific man. This fault has brought upon him much scorn and criticism, some not altogether deserved. But with all his violence and crudities, he is rich in inspiring suggestions, and I am truly sorry if any word of mine has harmed the reputation of a thinker for whom I have a great and sincere admiration.

W. H. S. JONES.

FEEDBACK AMPLIFIERS

By C. A. A. WASS

THE use of negative feedback to give improved performance in a number of important respects is now a well-established feature of amplifier design technique, and the simple mathematical treatment of an amplifier with feedback has been given by a number of writers. The earliest of these accounts was in a paper by Black[1], who showed that if an amplifier has a voltage gain of μ times, and an attenuating network is connected between the output terminals and the input terminals in such a way that a voltage equal to a fraction β of the output voltage is connected in series with, and in opposite phase to, the input voltage, the amplifier gain will be reduced in the ratio $1/(1-\mu\beta)$; but at the same time the distortion voltages for a given fundamental output will be reduced in the same ratio.

Besides reducing the distortion, negative feedback reduces the rate of change of amplifier gain with changing supply voltages, reduces some kinds of noise which originate in the amplifier, and can be used to flatten, or otherwise modify, the frequency response. It also has the effect of changing the effective impedance at points where the β circuit is connected to the amplifier, and has been used in this way to reduce the impedance of a pentode output valve so as to give better loud-speaker damping, and also to increase the input impedance of valves in high-frequency amplifiers.

It is clear, then, that negative feedback has great attractions for amplifier designers, especially as the explanations often given suggest that the application of feedback is quite a straightforward matter. It is only necessary, apparently, to feed back a voltage from the output terminals via an attenuating network to the input terminals, making sure that this voltage is in the 'right phase' to give reduced gain, and all the benefits follow automatically. Unfortunately, attempts to do this often result in the amplifier becoming unstable, particularly if more than a very modest degree of feedback is aimed at or if the effective frequency range of the amplifier extends above a few kilocycles per second. To understand this trouble, and to determine whether or not it can be overcome, a more rigid mathematical treatment than that mentioned earlier is required.

The simple mathematical treatment as usually given assumes—often tacitly—that μ and β are simple numbers, implying that neither the amplifier nor the feedback network cause any change of phase of the signals they transmit. Actually, although this may be approximately true near the middle of the working frequency band, phase-shifts always occur at higher and lower frequencies because changing phase is inseparable from falling gain. If the phase characteristics as well as the gain and attenuation characteristics of the amplifier and feedback network are taken into account, a much more useful and comprehensive statement of the effects of feedback can be obtained. Black's paper deals also with this more complex version of the problem, but the results seem to have received comparatively slight attention.

To find the effects of phase-shift in the amplifier, it is convenient to regard the quantity μ as a vector, of which the modulus $|\mu|$ represents the voltage gain of the amplifier and the angle represents the phase shift through the amplifier. Similar considerations apply to β. A signal which passes once through the amplifier and then once through the feedback network suffers a change of magnitude $|\mu\beta|$ times, and the corresponding change of phase is ϕ, say. ϕ does not include the fixed 180° per valve, which can be disregarded for the present purpose. It will be seen that $\mu\beta = |\mu\beta| \cos \phi + j\,|\mu\beta| \sin \phi$, where $j^2 = -1$.

The gain of the amplifier is still changed in the ratio $1/(1 - \mu\beta)$ when feedback is applied, but the quantity $(1 - \mu\beta)$ is now to be regarded as a vector. If the modulus of $(1 - \mu\beta)$ is called R, it will be seen that $R = |1 - \mu\beta|$ which is equal to ratio of gains before and after feedback is applied, and it can be shown that $R^2 = 1 - 2\,|\mu\beta| \cos \phi + |\mu\beta|^2$. This equation represents a family of concentric circles of radii R and centre at the point $(1, \hat{0})$. To interpret this equation a diagram is prepared by drawing a number of circles with radii greater than, equal to, and less than unity, with a common centre at the point $(1, \hat{0})$, using polar co-ordinates.

This simple diagram can be used to predict the change of gain resulting from the application of any degree of feedback to any amplifier under a fixed set of conditions provided that $\mu\beta$ is known completely, that is, provided that both $|\mu\beta|$ and ϕ are known. A line of length $|\mu\beta|$ is drawn from the origin at an angle ϕ, and the position of the end of this line with respect to the family of circles indicates the change of gain due to feedback. Thus if the line ends on the circle of radius 5, it means that the gain will be reduced by five times; if the line ends on the circle of radius 0·25 it means that the gain will be made four times greater; if the line ends on the circle of unit radius the gain will be unaltered when feedback is applied. It will be seen at once that the unit-radius circle is of special importance as the boundary between regions of 'negative' feedback, which reduces the gain, and 'positive' feedback, which increases the gain, and of course the region of positive feedback is restricted to points within the circumference of the unit-radius circle. This represents a considerable modification of the usual statement that feedback is negative when ϕ is in the neighbourhood of 180° and positive when ϕ is small or zero. This statement, while being useful as a rough-and-ready guide, gives no indication of what happens when ϕ is, say, about 90° or 270°; moreover, although it is true that feedback is always negative when ϕ lies in the neighbourhood of 180°, or more accurately between 90° and 270°, feedback is not always positive when ϕ is zero. Thus if $\phi = 0$ and $|\mu\beta| > 2$, the line representing $\mu\beta$ will lie along the reference line and it will end at a point outside the unit-radius circle. From what has been said before, this will correspond to a reduction of gain, that is, the feedback will be negative. This is a somewhat surprising result, and if a physical interpretation is sought, it seems at first sight that in an amplifier in which these conditions obtain the voltage fed back from the output terminals through the β circuit to the input terminals is more than twice as large as, and exactly in phase with, the input voltage, so that the net input voltage to the amplifier is apparently more than three times as great as before feedback was applied; yet the amplifier gain is reduced. The true explanation is that the phase of the output voltage is changed by 180° when feedback is applied, so that the feedback voltage is in opposite phase to the input voltage. This case is, of course, of little practical importance because it is difficult to realize the required conditions of $|\mu\beta| > 2$ and $\phi = 0$ in a stable amplifier. It is of interest, however, because it prepares the way for a complete statement of the conditions for stability in an amplifier with feedback. This statement is embodied in Nyquist's criterion, which can be explained with the help of the circle diagram.

Suppose in the case of an amplifier working under constant conditions with a certain degree of feedback, the value of $\mu\beta$ is known over the whole range of frequencies from zero to infinity. Now if a series of lines representing $\mu\beta$ at various frequencies is drawn on the circle diagram and a smooth curve is drawn joining the ends of these lines, the curve will form a closed loop beginning and ending at the origin, since $\mu\beta = 0$ at zero and infinite frequencies (direct current amplifier amplifiers being excluded). Nyquist's criterion, which is based on theoretical considerations, says that if the point (1, 0) lies inside the loop the amplifier will be unstable; if the point lies outside the loop the amplifier will be stable. The loop may have a complicated shape, and could, for example, have a lobe crossing the $\phi = 0$ line at two points beyond (1, 0), and it is seen that the case discussed earlier in which $\phi = 0$ and $|\mu\beta| > 2$ is theoretically possible in a stable amplifier.

As a check on Nyquist's work, Peterson, Kreer and Ware[2] built an amplifier in which the $\mu\beta$ loop had a lobe of this kind, and it was found to be stable.

In practical amplifiers it is often unnecessary to plot a complete $\mu\beta$ loop, and indeed a single point can sometimes be very useful. Thus, if the frequency at which $\phi = 0$ can be found and the value of $|\mu\beta|$ at this frequency is measured or calculated, it can generally be assumed that the amplifier will be stable if $|\mu\beta| < 1$ and unstable if $|\mu\beta| > 1$, since lobes are unlikely to occur in straightforward amplifiers. If $|\mu\beta| > 1$ at $\phi = 0$ it is often possible, by examining the loop in this region, to find some way of reducing $|\mu\beta|$ without appreciably affecting the performance of the amplifier in the working band. It must be realized, however, that for a given frequency band the degree of feedback possible in a stable amplifier is a fixed finite quantity which cannot be exceeded no matter what number of complicated phase-correctors and other devices are used. The estimation of this quantity is dealt with in a paper by Bode[3] which gives a complete method, based primarily on Nyquist's criterion, for the theoretical design of a negative feedback amplifier.

CONICAL REFRACTION

By SIDNEY MELMORE

Yorkshire Museum

An interesting paper on this subject by R. Potter appeared in the year 1841[1]. He "chiefly worked with an eye-lens, or else for micrometer measures with a compound microscope" and his conclusions (which are easily verified) are contained in the following passages: "The luminous ring is seen, and seen perfectly only, when the lens is so placed in its distance from the crystal, that what he [Lloyd] calls the two rays, are, in fact, the two virtual images of the luminous point on the first surface. The position of these virtual images within the crystal is found by the formulæ of geometrical optics, their distance from the second surface, when the incidence is nearly perpendicular, being equal to $\frac{\text{thickness of the plate}}{\text{refractive index}}$."

"Whether we draw the eye-lens away from the crystal, or push it nearer, we find similar appearances, and we see that the ring was formed by the intersection of two cones (or more correctly of two series of cones), the one converging so as to have the bright spot, we formerly found on the second surface, for its vertex, and the other diverging, and having the ring, formerly found on the second surface, for its base."

From these quotations it is evident that Potter was well aware of the possibility of extending the Duc de Chaulnes's method to the study of anisotropic media; but he gives no practical details, and the full development of this method is due to Sorby[2].

There is no reference to conical refraction in Sorby's papers; but they contain a description and figure of an effect directly due to it, which he left without investigation as a "curious appearance".

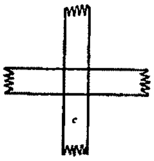

Fig. 1.

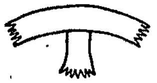

Fig. 2.

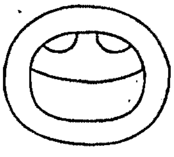

Fig. 3.

I observed the effects described below when using a plate of aragonite 8·1 mm. thick (cut approximately perpendicular to an optic axis) standing over a pinhole 0·09 mm. in diameter made in a piece of tin foil and viewed under a microscope provided with a 1-in. objective. When the crystal is set so that the refracted rays travel along the acute bisectrix, a cross is seen (Fig. 1); and when viewed through an analyser, first one bar and then the other is extinguished as the analyser is rotated, and the extinction takes place simultaneously at every point in the bar. On tilting the crystal about an axis perpendicular to the optic axial plane, one of the bars gradually becomes curved (Fig. 2). When the tilt amounts to about 6½° from the acute bisectrix it is apparent that the curved bar is no longer extinguished simultaneously at all its parts, and on closer examination it is seen that the extinguished part of the curve moves through double the angle that the analyser is rotated. By tilting about 8½° from the bisectrix, the appearance figured by Sorby is seen (Fig. 3). The ring is due to the hollow cone of rays diverging from a focal point considerably out of focus, and the centre of the figure represents the other focal point nearly in focus. The light of each cone is polarized according to the Hamilton-Lloyd law. By altering the focus, the figure changes into an elliptical ring. About 16½° from the acute bisectrix (that is, in the region of the optic axis), the cones from the two focal points intersect and form a ring approximately circular. In this position the two images of the pinhole lie one above and the other at a nearly equadistance below the plane of the ring and in a line nearly perpendicular to it.

No great accuracy is claimed for the angular measurements given above, but they are sufficient to show that the two features characteristic of conical refraction, namely, a curved wave-front and a particular state of polarization, appear soon after the acute bisectrix is passed and become progressively more complete and intense as we approach an optic axis. The Fresnel wave-surface accounts for a sudden change from point contact to circular contact of a tangent plane, but some modification of it seems necessary to account for a progressive change: what form this modification should take it is difficult to see.

After considering the subject of conical refraction, Stokes concluded: "We see, therefore, that the limitation of the number of tangent planes to the wave-surface, which can be drawn in a given direction on one side of the centre, to two, or at the most three, is intimately bound up with the number of dimensions of space; so that the existence of the phenomenon of internal conical refraction is no proof of the truth of the particular form of wave-surface assigned by Fresnel rather than that to which some other theory would conduct[3]."

Clifford hoped that useful results would flow from the application of the elliptic geometry of space: "I am", he wrote in 1870, "endeavouring in a general way to explain the laws of double refraction on this hypothesis, but have not yet arrived at any results sufficiently decisive to be communicated[4]."

No results are to be found among his published papers.

There is a rather obscure passage in Potter's paper suggesting the existence of a real focus outside the crystal, but it is doubtful whether this represents a record of observation or an inference from theory. Sir C. V. Raman has, however, recently obtained conclusive proof of its existence, and he finds that "the usual explanations of conical refraction do not go deep enough into the physical aspects of the problem"[5].

Hamilton himself wrote to Lloyd on January 1, 1833: "It is much for theory to have predicted the *facts* of conical refraction, but I suspect that the *exact* laws of it depend on things as yet unknown"[6].

CENTRAL SCIENTIFIC AND TECHNICAL BOARD

A MEETING was called by the Association of Scientific Workers on September 4 to discuss and support the proposals for a Central Scientific and Technical Board. These proposals had been the subject of a Motion on the Order Papers of the House of Commons for which, according to *The Times* of September 9, 126 signatures of members of Parliament had been obtained.

The papers and discussion at the meeting showed that more scientific workers and engineers consider that there is a real need for a Central Board to link science to the central direction of the War, and two main reasons were given. The first was that our scientific resources are not being used as efficiently as they should be. The question of duplication of work and the problem of those who consider that their work is not of immediate importance to the war effort, as well as the lack of consultation of technical staffs on technical questions affecting production, were all mentioned in this section. The second main contention was that as scientific and technical considerations permeate every sphere with which the War Cabinet must be concerned; that, as in fact science affects strategy and strategy must determine scientific development, it is essential that technical advice shall be immediately available to the War Cabinet.

Mr. A. L. Bacharach, in the chair, referred to the responsibilities facing the Association, not only to gain better conditions for scientific workers but also to improve the role of science in the community. Although the Association is a trade union, by virtue of the peculiar position enjoyed by science the Association has a moral obligation towards society, and cannot separate the status of scientific workers from the status of science.

Lord Strabolgi said that many of the present difficulties facing the United Nations are directly traceable to the fact that we have not yet begun to use fully the scientific man-power of the nation. In modern war, machinery and equipment have a tremendous importance and without them the bravest men are helpless. It is not a question of insufficient funds having been at the disposal of the Service Department but rather the question of the proper use of funds. He considers that only the Air Ministry has taken full advantage of science; not only has it got its own scientific departments but it has also drawn most freely on outside men of science. He paid a tribute to the rapidity with which the Admiralty has found remedies for new devices sprung upon us by the enemy, but holds nevertheless that the Admiralty suffers through being a closed department and not taking advantage of outside developments. We have greater scientific knowledge and experience in Great Britain than in the whole of the Axis Powers: it is only waiting to be used.

Mr. Swann, referring to the investigations made by the Association into conditions in industry and Government service, said these showed conclusively that in a number of important respects the scientific and technical resources of the country were not being used to the full in the war effort. In its proposals for improving the position the Association has received support from many other bodies and a number of detailed improvements have been made during the last six months. These have, however, not by any means fulfilled the stated need for better organization of scientific and technical workers.

Technology is concerned with the processes of manufacture and their improvement and is an essential factor in production itself. New developments are the constant concern of the research and development establishments under the Supply Ministries, in industry and the universities, and these developments need to be closely linked with production. Science is also concerned with the equipment when it is made, how it works in practice and what modifications are necessary. Science is also concerned with the community, its food, its health, its protection from air attack, etc. All these functions of science and technology are divided up in the various Government departments and industry; yet all these functions are related, and all are affected by the main strategy of the War. Strategical considerations determine which scientific problems are the most important; and conversely, the strategy of the War may be changed by scientific developments.

There is a great need for a body of scientific men who can indicate what assistance science can give to the development of strategy, who can interpret in technical terms the requirements of the strategy decided upon, and who can co-ordinate the scientific and technical work in the various Government departments and in industry. Such a body would need to be a full-time body, in direct contact with the War Cabinet, and with powers to obtain all necessary information on the resources and problems in the scientific and technical field; with the authority to initiate programmes of work and to have direct access to working scientists and engineers. The Association's proposals for a Central Scientific and Technical Board included these functions and powers. Mr. Swann pointed out that while many non-technical people spoke of men of science as 'inventors' the problem of the individual inventor is a special one, and is already very well provided for. Only a small proportion of the scientific discoveries made in this or any other country are due to individuals working on their own; the majority of discoveries are made by teams of workers in research and development establishments, either in Government service or in industry. It is these people who provide the bulk of scientific workers in Great Britain and with whom we are concerned in discussions of planning.

Other speakers from the platform and those who joined in the discussion from the floor all contributed arguments demonstrating the need for central planning in their own fields of work. Mr. D. T. Waigh spoke for men of science in industry, who, he claimed, represent the great majority of our scientific man-power. The scientific and technical staff have a fund of initiative and use it wherever they can; but they are often frustrated in their efforts through the existence of overlapping, lack of consultation and the feeling that their work is not co-ordinated into an effective whole.

Dr. D. McClean spoke of the need for planning in the biological sciences. He mentioned the absurd and damaging distinction between academic institutes and commercial undertakings, many of which are doing first-rate research and are at present the only organizations capable of translating laboratory processes into large-scale production. Bodies such as the Medical Research Council and the Agricultural Research Council are doing excellent work in their own institutes and by subsidizing research as well; but have never accepted responsibility for directing the national effort in the medical, veterinary and agricultural fields.

Mr. Innes spoke of the difficulties encountered by operational research groups, which are in general doing such good work. He considers that there is a need for combination between the different branches of the Services to avoid overlapping and waste of energy. The groups do not get sufficient guidance as to what is required, and for the efficient prosecution of their work they need knowledge of the research and production development that is actually being carried out on military equipment. Any central body must have its roots in working scientists and there must be close liaison with the scientists working for the Forces. To the working scientist it appears that there is not sufficient policy decision on how our scientific man-power should be used.

The day after the meeting reported above it was announced that three full-time scientific advisers had been appointed to the staff of the Ministry of Production (see Nature of September 12, p. 301). While the Association welcomes these appointments as a step to link science with production, it is certainly not clear from the official announcement whether the scope of activities of the three advisers will be wide enough to answer the demand for a Central Scientific and Technical Board. Questions which are bound to be asked are: what powers the advisers will have to get information and to put their recommendations into practice, whether it will be possible to extend their work to include the scientific and technical activities of the Service Departments and other Ministries outside the strict field of production, what the position of the Lord Privy Seal will be in supervising the work of these advisers, and their relationship with the War Cabinet and the Minister of Production. Until these and other questions are answered in practice, those who have supported the call for a Central Scientific and Technical Board will no doubt continue to voice their demands for something wider than the appointment of advisers to a single Minister.

FORTHCOMING EVENTS

Saturday, September 26

Society of Chemical Industry (Joint Meeting of the Manchester Section and the Food Group) (in the Reynolds Hall, College of Technology, Manchester), at 2.30 p.m.—Dr. L. H. Lampitt: "The Preservation of Foodstuffs".

Monday, September 28

Society of Chemical Industry (Yorkshire Section) (in the Chemistry Lecture Theatre, The University, Leeds), at 6 p.m.—Dr. E. C. W. Smith: "Incendiary Materials".

Thursday, October 1

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Prof. C. L. Fortescue: Presidential Address.

Saturday, October 3

Geologists' Association (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. David Williams: "Mineral Resources of the U.S.S.R.".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Chemistry—The Registrar, The University, Manchester 13 (September 30).

Principal Teacher of Engineering (Mechanical and Electrical) in the Technical College, Coatbridge—The Director of Education and Deputy County Clerk, Lanarkshire House, 191 Ingram Street, Glasgow, C.1 (October 2).

Teacher of Electrical Engineering—The Principal, Wolverton Technical College, Wolverton, Bucks. (October 3).

Assistant Lecturer in Mechanical Engineering—The Registrar, College of Technology, Manchester 1 (October 5).

Lecturer in Mechanical or Electrical Engineering in the Cannock Chase Mining College—The Director (H), County Education Offices, Stafford (October 14).

Assistant Master to teach Machine Shop Practice, Theoretical and Practical—The Principal for Further Education in Gillingham, Medway Technical College, Senior Departments, Gillingham.

Lecturer (man or woman) in Mathematics for the Junior Technical School for Boys—The Secretary, Woolwich Polytechnic, Woolwich, London, S.E.18.

Steward for Organic Chemistry Department—The Laboratory Superintendent, Chemistry Department, Imperial College of Science and Technology, South Kensington, London, S.W.7.

WAR-TIME USES OF ANTHROPOLOGICAL SURVEYS

DARWINISM affected the study of the racial classification of man in various ways. It offered a plausible hypothesis to account for the diversity observed within the species, and anthropologists soon realized that new descriptive data would be needed to test the theory at all effectively. The systematic collection of records of the physical characters of samples representing different populations began about 1860. Techniques were laid down defining measurements and observations to be taken on series of living people and skeletons. The characters used earlier were principally certain measurements of the head and body, and records of skin, hair and eye colours. The list was supplemented by blood groups after the War of 1914–18. The advantages of a statistical treatment of both the quantitative and qualitative data are now generally appreciated.

Owing to the lack of any effective international agreement regarding matters of technique and planning, the anthropological records are far less useful than they might have been made with the same expenditure of labour. Nevertheless, they form a substantial bulk of reliable evidence, though ways in which it should be treated and interpreted for taxonomic purposes are still highly controversial. In the past eighty years, anthropological surveys of living populations have been carried out on larger or smaller scales in most parts of the world. The evidence is distributed in a very uneven way, some regions being well described while others are badly documented. In Europe nearly all the investigations have been of a national kind, the two most comprehensive being for Sweden and Norway. Shortly before the present War, Harvard University sent an anthropological expedition to carry out a survey of the people of Ireland, which was almost an untrodden field. The results have not been published yet. England is among the European countries the populations of which are least well known from the same point of view.

It has repeatedly been urged that surveys of the physical characters of national populations should be carried out for other purposes. Most of these come within the scope of 'race biology'. Official demographic and medical statistics give some indication of the biological condition of a people, but they leave many questions unanswered. The announcement that the British Army Medical Service had great difficulty in obtaining a large enough number of men of adequate physique for service in the South African War was a revelation. Much discussion of national degeneration followed, but there was little scientific evidence bearing on the topic. The report published in 1920 on data for recruits collected two years earlier again disclosed a disquieting situation. About the same time special inquiries of limited scope were undertaken which revealed the prevalence of malnutrition and some of its effects on physique.

There is still an urgent need for a survey which will assess the physical fitness and capabilities of the population of Great Britain. Physiological and medical tests and observations are the data principally required in this connexion, but the customary anthropological characters should be recorded as well, since it is necessary to make allowances for racial diversity in interpreting the import of regional and class differences. It is significant that the first major task undertaken by the Swedish State Institute for Race Biology was a purely anthropological survey of 47,000 conscripts from all parts of the country. Knowledge of that kind is of basic importance in many connexions.

The medical information gained from the examination of recruits is of immediate military importance. So also have been the few body measurements usually recorded at the same time. They have been used principally to determine limits of height and weight taken into account when deciding whether men should be rejected or assigned to a particular grade. All fighting services have fixed minimum statures for entrants to different forces. Measurements of recruits collected in several European countries in the past century revealed the fact that there has been a secular increase in the average statures of many populations. Hence it was necessary to change the standards adopted from time to time.

In some countries body measurements have doubtless been used extensively for other military purposes to which there is scarcely any reference in the literature of anthropology or any other science. They should obviously be of assistance in connexion with the supply of clothing and equipment. There are two kinds of problems encountered here. The first is concerned with the provision of things worn by the men. In the case of clothes of ordinary kinds, the ranges of shapes and sizes needed, and the relative frequencies with which they are required, are known to the manufacturers on account of their extensive experience. In the case of articles designed for special purposes, however—such as helmets worn by airmen, or equipment carried by infantrymen—there may be no such guidance. A trial-and-error method of gaining the experience required is likely to be slow and wasteful. Measurements already recorded for anthropological purposes would probably be found to aid particular specifications to greater or lesser extents. If they are not sufficient, it should be profitable to take new measurements on a suitably chosen sample of a few hundred men. In cases where accurate fitting is a matter of considerable importance, a special investigation might be needed to discover whether the manufacture of standard sizes can give satisfactory results, or whether the article should be made to measure.

The second kind of supply problem referred to concerns the allocation of men to confined spaces of particular dimensions, such as the compartments of aeroplanes, tanks and submarines. Ideally, it may be considered most expedient to take body measurements into account when designing such conveyances. If they have been made with no detailed regard to that factor, then it is still desirable that body measurements should be used in deciding which men should be assigned to particular duties, so that their accommodation, and the efforts they make in reaching controls, cause no avoidable discomfort or strain. Metrical data available could certainly be used with advantage in this connexion, but additional records might be needed to give entirely satisfactory results.

It may be suggested that there can be little practical advantage in discussing these matters now, since nothing approaching a comprehensive anthropometric survey of the population of Great Britain, or any large section of it, has ever been undertaken. Neglect of such research can be attributed partly to good fortune in being almost free from racial disputes and animosities within Great Britain, and partly to the fact that only small fighting forces were maintained in peace-time. A committee of the Ministry of National Service published a report on part of the evidence collected by the medical boards during the War of 1914–18. Data were included for three measurements—height, weight and "chest expansion"—but the way in which they are presented is statistically inadequate. Officialdom has cared little for these things.

In June 1939 a committee of the Royal Anthropological Institute was set up for the purpose of urging the authorities to take advantage of the opportunity offered of collecting scientific evidence in connexion with the medical examination of recruits called up under the Military Training Act. Its principal concern was in advocating that a few body measurements and observations should be taken on some 30,000 men, to obtain an adequate knowledge of the racial constitution of the population of England, Scotland and Wales. Repetition of the measurements was urged, so that the effect of training and standardized diet on physique could be estimated. At the same time, efforts were made to interest certain other bodies which might have collaborated in the inquiry and extended its scope by adding tests and observations of physiological and genetical significance. The outbreak of the War led to the suspension of negotiations which had encouraged the hope that the scheme would receive official backing. Attempts to revive it later were unsuccessful, although the information which might have been obtained by such means was needed more urgently once hostilities had started.

In some respects nothing can compensate for the absence of an anthropological survey. If it is lacking the diversity within a population due to differences in the origins of its component sections is unknown, and the extent to which any regional or class differences should be attributed to the racial factor must remain a matter of surmise. In spite of these limitations, it is possible to apply some of the data obtained from the survey of one country to the population of another country, to give the kind of information required in connexion with supply problems. For example, the body (excluding the head) measurements of the populations of Western Europe indicate distinctions in size rather than shape. So far as is known, the relative proportions of the limbs and trunk, or segments of them, are remarkably constant for these populations, and a close approach to equality is also found in variation and correlation. If data for stature, but for no other character, are available for a particular one of the countries, then it is possible to predict a great deal of information regarding other characters of its members by applying results derived from the surveys of other countries. This is a statistical matter, and the scope and accuracy of the predictions referred to could be investigated adequately by treating extensive material available in the anthropological literature.

The population of the British Isles has remained unsurveyed by anthropologists, though records of the statures, at least, of large numbers of men of military age must have been determined in recent years. It is fortunate that extensive anthropometric surveys have been carried out for two allied populations, namely, the Swedish and Norwegian. In fact, these two have been better described in the respect considered than any others in the world. With proper reservations, the results for them could be applied to men from the British Isles to give information required for military purposes. There are several other ways in which knowledge and experience gained by physical anthropologists might be applied immediately to certain military problems in the interests of economy and efficiency. It may not be proper to ask what has been done already in this direction, but there can be no impropriety in suggesting that this is a matter which should be given careful consideration by those responsible for the Government's policy on the use of scientific and technical resources.

The need seems to be for an advisory committee which could deal with all questions of the kind referred to. Such a body should include anthropologists with knowledge of the relevant literature and experience of techniques used in measuring human beings, and statisticians who would ensure that the data were used in the best way. One of their first tasks might be the reduction of body measurements already taken of men serving in the Fighting Forces. Information derived from them should be presented in a concise and convenient form to those requiring it who are concerned with production and the assignment of men to particular duties. The value of published anthropometric records for the same purposes could also be considered, and the committee might seek permission to use the data collected in certain unpublished surveys of sections of the British population which have been carried out for academic purposes. It could be called on to deal with any new problems falling within its scope, and should be given power to undertake new investigations involving the measuring of samples of the populations concerned. The primary aim would be the speedy solution of problems connected with immediate war-time needs; but it is not to be doubted that the information and experience gained would later be found to be of scientific value in elucidating certain problems of medicine and race biology which are also of great importance to the State.

WORLD CO-OPERATION IN PRODUCTION, CONSUMPTION AND DISTRIBUTION

SIR STAFFORD CRIPPS'S address on July 25 at the Conference on Mineral Resources arranged by the Division for the Social and International Relations of Science of the British Association was noteworthy as an indication that the Government is willing and eager to meet the challenge of a remarkable series of speeches recently made by leading American statesmen. The views expressed by Mr. Wallace, Mr. Milo Perkins and Mr. Sumner Welles in May, by Mr. Winant at Durham in June, and by Mr. Claud Wickard, Mr. Dean Acheson and Mr. Appleby in July, all of whom are intimately concerned with the formulation of American policy, may be taken to represent official thought in the United States on the problems of post-war reconstruction. Sir Stafford Cripps, in welcoming these beginnings of an interpretation of the generalities of the Atlantic Charter, was clearly speaking for the Government, and in promising "willing co-operation along the paths which they indicate", he carried a stage further the promise made earlier in the same week by Mr. Eden and Sir William Jowitt.

The keen interest in these pronouncements betokens the general sympathy in Great Britain with the American agreement and the desire that British leaders should take their full share in formulating future policy on these lines. In Great Britain as in the United States, war is seen as part of a continuous process the roots of which lie deep in poverty, insecurity, starvation and unemployment, and this War will not be really won until the deep causes of war have been uprooted. As Mr. Winant says, this is no short-term military job: "To crush fascism at its roots we must crush depression democracy. We must solemnly resolve that in our future order we will not tolerate the economic evils which breed poverty and war. This . . . is part of the war. . . ."

This new thesis, this deeper view of social and international responsibility, which goes down to the foundations of society in seeking to discover the causes of such manifestations of social disease as totalitarian war, is quite incompatible with isolationism, which it would eliminate, not only on the grounds of world solidarity and comradeship but also of plain self interest. It involves a moral revolution which Sir Stafford Cripps did well to emphasize. Warmly as these views are welcomed, it would be a disaster if there were any failure to understand the sacrifices and changes which will be demanded if the principles of the Atlantic Charter are to become more than pious aspirations. The reports of the Chambers of Commerce, the National Union of Manufacturers and the Federation of British Industries, all issued in the same period, are both measure and warning of the opposition, the prejudices and the difficulties which have to be overcome.

It is, of course, only in broad outlines that the solution is sketched in the speeches made by the American statesmen. Mr. Wallace, referring to

America's opportunity, suggests that the century on which we are entering will be known as the century of the common man. It may be America's opportunity to suggest the freedoms and duties by which the common man must live; and modern science, when devoted wholeheartedly to the general welfare, has in it potentialities of which we do not yet dream. But the will to peace and the continued co-operation of the United States and Britain form the political framework. No nation will have the God-given right to exploit other nations. Older nations will have the privilege of helping younger nations to start on the path to industrialization, but there must be neither military nor economic imperialism, and modern science must be released from German slavery. There can be no privileged peoples, and there will be the supreme duty for the citizen of sacrificing the lesser interest for the greater interest of the general welfare. Moreover, as Mr. Cordell Hull puts it, we must no longer ignore the simple but fundamental fact that the price of peace and of the preservation of right and freedom among the nations is the acceptance of international responsibility.

Mr. Welles, in his address, suggested broadly a long armistice, the disarmament of the aggressors, a United Nations police force, and finally the United Nations as the nucleus of a world organization to determine the final terms of a just, an honest and a durable peace as successive stages. This approach to political and military security springs from that new conception of the deep causes of war and of the new and dynamic conception of post-war relations which finds such vivid expression in Mr. Winant's great speech at Durham. The scientific and economic resources which produce the weapons of war can produce in as great a measure the instruments of peace.

"We have enough technical knowledge and organizing ability to respond to this awakening of social conscience. . . . When war is done the drive for tanks must become a drive for houses. The drive for food to prevent the enemy from starving us must become a drive for food to satisfy the needs of all people in all countries. The drive for physical fitness in the Forces must become a drive for bringing death and sickness rates in the whole population down to the lowest possible level. The drive for man-power in war must become a drive for employment to make freedom from want a living reality. The drive for an all-out war effort by the United Nations must become a drive for an all-out peace effort based on the same co-operation and willingness to sacrifice."

It is not beyond our technical or spiritual capacity, Mr. Winant continued, to have these basic things, and his speech gives noble expression to the expansive, purposeful concept of economics which underlies the new American outlook, the philosophy of what Mr. Sumner Welles calls "the frontier of human welfare". The key is expanding markets, a "mass consumption great enough to use mass production", "a future planned in terms of increase and not curtailment". Within the broad framework, private enterprise and free trade—the progressive sealing down of trade barriers and the end of all discriminating measures—are to be the chief instruments of economic advance, though some measure of Government control is envisaged, and Mr. Milo Perkins speaks of "a bold and daring use of long-term credits by Governments entering fields where private finance cannot enter without taking risks that are too great to take with other people's money".

There can be no doubt as to the revolutionary character of the policy advanced in these speeches. They represent a new conception of world order and an inspiring attempt to reinterpret democracy in terms of the twentieth-century situation and to extend its meaning in the economic and social sphere much as Lord Elton has done in "St. George or the Dragon". But it must be recognized that while this call for a co-operative venture, broadly based on the idea of the United Nations, comes from the progressive elements in the United States, there are powerful interests as well as many individuals who do not accept the thesis of co-operation.

For this reason the speeches of Sir Stafford Cripps, Mr. Eden and Sir William Jowitt were specially welcome. Sir Stafford Cripps rightly emphasized the moral revolution which is required if the principles of the Atlantic Charter are to become more than mere platitudes. Behind our scientifically prepared plans there must be, he urged, the inspiration of our deepest religious convictions. That will carry us along the road on which our feet have already been set in developing the plans of the United Nations for their war effort—the subordination of private and national interests to the public and international good.

The determined change of outlook from that of competition to that of co-operation will be as imperative after the War as for its prosecution, and without that outlook we may fail once again to carry over into the work of building the peace the organization for pooling material and experience developed for winning the War. Much of that may well serve eventually as the foundation of a permanent system of international management, and this series of speeches in Great Britain and in the United States of America should be welcomed first for its contribution to the education of public opinion to the sacrifices in private and sectional and national interests which will be involved. Neither Mr. Eden nor Sir Stafford Cripps failed to indicate the extent to which it is in the hands of the people of both countries how far this great experiment of Anglo-American co-operation can be continued after the War, and the necessity for a moral basis.

In associating himself with the hopes inspired by the American speeches, Mr. Eden pointed out that the solution of this problem of organizing full production and equitable distribution of what is produced would demand not only hard work and goodwill but also political invention of a very high order. The new problems cannot be solved along the old lines. In view of the caution and conservation of some of the industrial reports, it is all the more encouraging that Lord Simon, speaking in the House of Lords, should declare that we do not intend to be bound by the orthodoxies of the nineteenth century, and he emphasized that passage in President Roosevelt's report to Congress on June 11 on Lend-Lease operations in which the President asserted that the financial costs of the War can and should be met in a way which will serve the needs of lasting peace and mutual economic well-being; he also declared the Government's full agreement with the statement and its conviction that it provides a firm and solid basis for co-operation with the United States in winning the peace. The principles of expanding consumption and rising standards of living are also discussed by Mr. Walter Elliot in a recent thoughtful article in which he elaborates the theme of making them the foundations of an ordered and prosperous international community after the War, starting from the point made by Mr. Milo Perkins that our civilization is commodity-rich and consumption-poor. The interest aroused by the British Association Conference on mineral resources and the Atlantic Charter shows how public opinion in Great Britain is becoming aware of what is involved, and is prepared to support that survey of needs which must follow the research into the extent of world resources, of the methods of making them available and of placing them at the disposal of those who need them.

All this is required as a basis for action, and beyond this question of production there lie the even more baffling problems of distribution and consumption. The recent speech of Mr. Nash, Finance Minister of New Zealand, who had early suggested the creation of a World Reconstruction and Development Council through which a positive programme could be mapped out for carrying on a world of peace, contained a friendly warning which we do well to heed. He referred to our failure to give full weight to post-war reconstruction and development, which is the major aim of a large and influential section of the American people. Moreover, his concern that the whole management of the national war effort is being seriously handicapped by excessive reluctance to interfere with existing channels of production and trade applies equally to reconstruction.

The discussion on economic reconstruction after the War, opened by Mr. R. G. Glenday before the Royal Statistical Society on March 17, which has now been reported in the *Journal* of that Society, makes a timely appearance as a corrective to facile optimism which might be engendered by these pronouncements. Mr. Glenday insisted that changes in the business environment must be scientifically analysed and understood before any useful work could be done in planning for post-war reconstruction. He suggested that a factual examination of the condition of Britain's economic environment during the two pre-war decades would show that the change from Free Trade to Protection in 1931 was largely forced upon us by influences outside the individual control of governments. The major factors in precipitating this economic revolution, of which the present War should be regarded as part are, in Mr. Glenday's judgment, the closing of the age of territorial expansion, and the slowing down in the rate of population growth in the more developed and wealthier countries, coupled with continuing expansion in the less mature; and the failure to appreciate that, even though an economic system may not be consciously planned, it must in its process of growth conform to certain rules of order and structure if it is to avoid breakdown. In particular, the rates of growth of its separate parts must be kept in proper relation to one another, and for every structure there will be a most convenient size.

Mr. Glenday was clearly somewhat pessimistic as to the ability of industry to continue automatically to provide expanding avenues of employment, but while he pointed out correctly that the problem is that of creating new avenues of employment fast enough to absorb those thrown out of work by technological developments of a labour-saving kind, he appeared, as Prof. A. C. B. Fisher observed, to accept as axiomatic without further question that the obstacles he indicated were irremediable. Mr. Glenday did indeed suggest that the new comradeship of effort brought into being by the War may be the only solid foundation that we shall possess on which to build that new world for which so many are yearning, but his reference to the Atlantic Charter was scarcely constructive. Both Sir William Beveridge and Mr. Stanley Jevons joined issue with Mr. Glenday on these points, as indeed did Sir Gwilyn Gibbon, in whose brief appeal for concrete proposals rather than generalities lie the untold possibilities of further scientific advances. Sir William Beveridge, speaking from the chair, insisted that it is in our power to abolish want and to cure the evil of urban congestion, provided that we win the War and make such a reasonable contribution towards winning it; that the rest of the world would be friendly; that the nation wills these changes sufficiently to override the various vested interests; and that the changes are adequately planned. The transition problems would undoubtedly be harder to deal with at the end of this War, and Sir William urged that we should pay at least as much attention to problems of which the solution is within our power as to those of which the solution requires an international agreement.

There should be a generous response to the wider understanding, the quickened sense of human sympathy, and recognition of the common purpose of humanity which finds expression in both British and American speeches, and men of science will be able, by virtue of their training and outlook, to bring careful scrutiny to bear on the concrete proposals which may be formulated. But if scientific men, who have been brought up in an atmosphere of international co-operative development, can, as Sir Stafford Cripps pointed out, do much by their example and advice to create this new and challenging spirit among the free peoples of the world, there is one contribution they are supremely competent to make. From none better than from those who have devoted themselves to science, to the search for truth, can the free peoples acquire the habit of facing change fearlessly and bringing to the solution of our great problems of production, consumption and distribution that same adventurous spirit and willingness to accept new ideas and new ways by which science has won its triumphs.

FACTORY INSPECTORS AND THEIR WORK

Factory Inspection in Great Britain
By Dr. T. K. Djang. (London School of Economics and Political Science: Studies in Political Science and Sociology, No. 2.) Pp. 256. (London: George Allen and Unwin, Ltd., 1942.) 12*s.* 6*d.* net.

WHEREAS the work of the factory inspectorate in Great Britain has been very little affected by the transfer of the Factory Department in June 1940 from the control of the Home Office to that of the Ministry of Labour and National Service, the transfer indicates the great importance of factory inspection at the present time, and this first full-length study of the system to be published in this country is opportune. Dr. Djang's book traces the history of the inspectorate, describes its organization and explains the functions and methods of the inspectors. Moreover, the book is admirably annotated and is of real value, not only for an understanding of the work of factory inspection from the point of view of the general citizen, but also as a guide to many of the regulations under the Factory and Workshops Act and to the functions of the inspectorate for those who, in war-time, have been brought into closer contact with them. The bibliography is comprehensive and well arranged, though it might well have included more explicit reference to the excellent review of the work of the inspectorate during 1833–1932, which appeared in the annual report of the Chief Inspector for the year 1932. In the main, Dr. Djang's book is descriptive rather than critical, but the picture he gives leaves no one in doubt that the success of the factory inspectorate in Great Britain has been due largely to the inspectors themselves and to the extent to which they have succeeded in securing the co-operation of both employers and employees. There could scarcely be a better illustration of the value of the principle that in legislation the channels of assent should be dug deep.

It is a tribute to the wise use the inspectors have made of the great powers they possess that they succeeded in establishing so speedily their position as rather that of expert advisers than mere vigilance officers. One of the most interesting aspects of the factory inspection service is, indeed, the example it affords of the application of expert advice on matters of industrial and indeed public welfare. For this reason alone, Dr. Djang's book should be of wide interest to scientific workers, and not the less for the illustration it gives of the value of the system in educating both factory workers and the general public. The wise use of publicity made by the Factory Department, to which Dr. Djang directs particular attention, is only now becoming fully recognized, as indeed is indicated in the recent movement for the establishment of production committees and other methods of promoting industrial morale.

A further factor in the success of the system on which Dr. Djang lays some stress is the utilization of outside expert assistance. The Factory Department has worked in close collaboration with the National Institute of Industrial Psychology, the National Safety First Association, the Industrial Welfare Society, the Home Office Industrial Museum and the Industrial Health Research Board, of which only the last two are Government establishments. The work of the Department is probably weakest on the research side, and several recent reports have commented on the unsatisfactory state of research in the field of industrial health, notably those of the Select Committee on National Expenditure and of the British Medical Association's Committee on Industrial Health in Factories. Dr. Djang suggests that, to avoid overlapping, all research work on factory health and welfare should be entrusted to the Industrial Health Research Board, except that which the Factory Department considers could be conducted by the factory inspectors with greater convenience and better results. As to the need for greatly extending the vigour and resources with which such work is prosecuted, Dr. Djang's book leaves no room for doubt, and the Industrial Health Research Board should clearly be used as the Select Committee recommends and endowed with adequate resources. When all allowance has been made for the research in this field which the work of the Factory Department has already stimulated on the part of private firms, the value of such a central research organization cannot be questioned. Moreover, Dr. Djang's book emphasizes once more the extent to which the real problem of safety and health in industry is centred in the small firms where the management possesses neither the technical knowledge nor resources to cope with the problems unaided and unguided.

The suggestions which Dr. Djang himself advances for the improvement of the service are somewhat unequal. Of those affecting the reorganization of the Factory Department itself, those for investing the Chief Inspector with wider powers inside the Home Office than he at present wields, and in regard to the provision of an effective central information service, are the most convincing. Dr. Djang does not indeed mention some of the prime needs which the latter department might serve. The collection and systematization of information on accidents and matters affecting industrial health and safety are far from satisfactory, and the field is still very imperfectly covered, even from published literature, by existing periodicals. A central information department such as he suggests, which could surely count on all sources of official and unofficial as well as published information, should make a very real contribution to the important field of industrial health and accident prevention. There is nothing on the chemical side corresponding with the "Index Medicus", and the utility of the latter is very seriously impaired by the indifference to such matters as chemical nomenclature of medical men and their periodicals.

Dr. Djang also suggests the encouragement of foreign travel by the inspectors and the transfer of medical examination of young persons for factory employment to school medical officers, with regard to which it should be noted that an important section of medical opinion considers that the duties of the school medical officers can now largely be transferred to the general practitioner. Again, while chemists are already often to be found in the ranks of the inspectors, it is difficult to see what would be gained by the formation of a specialized branch of chemical inspectors as suggested by Dr. Djang, or what the recruitment of a section of industrial psychologists could do that could not be done equally well or better by means of the existing relations with the National Institute of Industrial Psychology. Of other suggestions made by Dr. Djang may be noted his plea for more educational work in the factories among the workers, employers and the general public, the study of labour problems from a wider field than that of the factory, and closer co-operation between the Factory Department and the International Labour Office. Mr. W. A. Robson's admirable introduction directs attention to an important point upon which the success of the system, however, may largely depend, although it is almost passed over by Dr. Djang, namely, the action of the courts in enforcing factory legislation, although the book includes examples of the failure of magistrates adequately to enforce the law and impose penalties for its breach.

As a contribution to the wider education of public opinion and the sympathetic understanding of the work of the Factory Department, upon which the effective support of its work, either in the factory or on the bench depends, this volume should be warmly welcomed. From scientific workers it well merits further attention as a highly suggestive study of a system in which scientific officers can render technical service to the State on terms which permit them to retain their professional independence and integrity.

R. BRIGHTMAN.

ROMANTIC GEOLOGY

Biography of the Earth

Its Past, Present and Future. By Prof. George Gamow. Pp. xiv+242+27 plates. (New York: The Viking Press; London: Macmillan and Co., Ltd., 1941.) 12*s*. 6*d*. net.

IN his book on "The Birth and Death of the Sun", Prof. Gamow revealed himself as a witty and enthusiastic writer with a remarkable flair for successfully popularizing current problems of stellar evolution. He has now applied his lively style of exposition to the life-story of the earth. The book deals broadly with the age and origin of the earth; the birth of the moon; the internal structure of the earth; the origins of mountain ranges and continents; climatic changes; the origin and evolution of life; and the final melting of the earth "in the last desperate explosion of its dying parent"—the sun. The narrative is as vivid and exciting as before, but this time, unfortunately, it is no longer sustained by an adequate background of expert knowledge. In consequence the book is seriously marred both by carelessness as to facts and by an uncritical adoption of many highly speculative hypotheses.

Thus the old view that the Pacific is the scar left by the birth of the moon is accepted—and correlated with the restricted area of the continental masses—without giving the reader any hint of the grave difficulties which stand in the way of this otherwise attractive solution of one of the fundamental problems of geology. Nor is any mention made of alternative hypotheses bearing on the origin of the continents. The author does not appear to have heard of the convection hypothesis, as he fails to mention it either in this connexion or in relation to any of the other problems raised by the major relief and pattern of the earth's surface. Few geologists would now agree with Gamow that "there is hardly any doubt" that great mountain ranges are wrinkles of the crust formed in response to the contraction of the underlying plastic layers. Indeed, the remarkable illustrations on p. 119, purporting to show how mountains are formed, and recalling Descartes's highly erroneous conception of mountain structure (NATURE, July 2, 1938, Suppl., p. 26), clearly demonstrate that the process, as imagined by Gamow, produces nothing remotely like actual folded mountains.

It is a pity that the book was not 'vetted' by a geological friend before publication. Apart from controversial matters, we might have been spared "metamorphized" for *metamorphosed*; "crumbling" for *crumpling*; and such infelicitous statements as "the volcanic eruptions . . . were ejecting masses of molten granite". Occasionally the author is more humorous than he intended to be. On p. 145, for example, he tells us that "the name 'Cambrian' indicates simply that the deposits of that period were first discovered and studied in Cambridgeshire (England)". Another gratuitous blunder is the statement (p. 186) that Gunz, Mindel, Riss and Würm are the names "of the geologists who studied various advances of ice and after whom these periods are often called".

Read as a 'thriller', Gamow's book is highly entertaining; but the reader who knows little geology to begin with must be warned not to take it too seriously. As an imaginative biographical novel it has undoubted merits and teachers will scarcely fail to profit from its originality of treatment. But as a scientific description of the earth's evolution it is in many respects inaccurate and misleading.

A. HOLMES.

LAND DRAINAGE

The Principles of Field Drainage

By H. H. Nicholson. Pp. xi+165+12 plates. (Cambridge: At the University Press, 1942.) 12*s*. 6*d*. net.

BEFORE the outbreak of war the National Farmers' Union estimated that a quarter of the farm land of England and Wales could be improved by drainage. Since then a series of measures taken by the Ministry of Agriculture enables drainage work, approved by county war agricultural executive committees, to receive a 50 per cent Government grant. A start has been made on this urgent work but much still remains to be done, and a book on the principles of field drainage is to be welcomed at this time.

Mr. Nicholson and his colleagues in Cambridge have made a special study of the drainage of an area of heavy gault clay soil acquired by the University Farm in 1930, in a derelict state, and afterwards rehabilitated by mole drainage. Their careful observations of the effects on the soil structure produced by the passage of the mole plough points the way to large-scale improvement of our heavy lands by mole drainage now that the development of the powerful track-laying tractor has reduced the cost. They found that this clay soil is fissured to the depth of the channel for a distance of two or three feet on either side of it. This observation has helped to elucidate the process by which drainage water reaches the mole channels. Clay subsoils always tend to return to their natural condition, and mole drainage is essentially a cultivation operation which must be repeated at intervals. As such, it is a means by which a system of tile drains at a lower level may be kept in operation or even restored to working order.

The author does not deal with the technicalities of surveying or of drainage engineering. His aim has been to interest and assist those who have to devise, advise on, and supervise works of field drainage. He classifies the conditions under which ditches and drains are needed and discusses the different ways in which drains are laid. An account of the moisture properties of soil leads to a general description of the way field drains work.

While part of the text is new, several sections are reprints of articles and leaflets published from 1936 onwards. In consequence of this method of compilation there is unnecessary and tiresome repetition. A more logical development could have been achieved had the whole been written anew. Nevertheless this little book can be thoroughly recommended to the public for which it is written. It is well illustrated by plates and text-figures and is a valuable addition to the scanty bibliography of an important subject.

R. K. SCHOFIELD.

APPLICATION OF THE STUDY OF VIBRATION TO ENGINEERING DESIGN

Fundamentals of Vibration Study

By R. G. Manley. Pp. xii+128. (London: Chapman and Hall, Ltd., 1942.) 13*s*. 6*d*. net.

ACCORDING to the author's preface, this book is intended to be an introduction to vibration theory. The result, however, is in some respects not so much an introduction as a summary of material that is more amply discussed in the standard treatises.

Beginning with one degree of freedom and the effects of forced vibration and damping, the author passes on to two degrees of freedom, many degrees of freedom, continuous systems and complex vibrations. What is said about these matters is doubtless perfectly sound, but a book of this type stands or falls by the method of presentation rather than by the matter presented, and it must be recorded that the method here adopted, apart from a little amplification here and there, follows closely that of the standard text-books on the subject. It may be objected that the difficulty of presenting a subject of this nature from a new angle is a very real one, but the fact remains that there is little here to give the learner a clearer insight into vibration theory than he can pick up from the fuller work of Den Hartog, for example.

A more serious criticism of this book is that the author attempts too much. He tries to expound vibration theory and the necessary mathematics at the same time. It just cannot be done. According to the author, "no previous knowledge of differential equations is assumed, this troublesome part of the theory being dealt with by the powerful and easy method of operators" (which only means the standard *D* notation) and only a little more than matriculation mathematics is necessary. In view of the fact that the treatment covers such matters as the differential equation of the beam flexure and the use of Fourier series, the above statement is misleading. The gap is supposed to be bridged by a five-page appendix on "Some Pure Mathematics", and an eight-page appendix on "Some Applied Mathematics"; but the bridging is wholly inadequate.

As the avowed object of this work is to smooth the path of the beginner it is a pity that obsolescent, if not obsolete, units like poundals are mentioned neither the engineer nor the scientific worker has any use for the poundal. Also one feels that the introduction of a mass unit equal to the mass of 386 lb is more confusing than helpful. What is wrong with the slug, that is, the mass of 32·2 lb.? The learner will have no difficulty in converting inches to feet when I and E are given in inches.

One curious error must be pointed out, as it wil most certainly confuse the learner. On p. 8 we hav the statement

$$\text{“}m = \frac{\text{lbs.}}{g} = \text{lbs. ins.}^{-1}\text{ sec.}^{-2}\text{”.}$$

Obviously the symbol g stands here for the *ratio* o gravity acceleration to unit acceleration and is nondimensional, so that after division by g the dimensio is still that of mass, although now in slugs instea of pounds. This error is repeated twice in Appendi II where we find the statement,

"1 lb. wt. = g poundals,
where g has the value 32·2 ft./sec.^{2}".

Clearly, for plain dimensional consistency this ough to read, "where g has the value 32·2".

The inclusion of a few exercises at the end of eac chapter is a good feature that is enhanced by printin the answers at the end of the book.

PASTURE MANAGEMENT

Back to Better Grass

By I. G. Lewis. Pp. 68. (London: Faber and Fabe Ltd., 1942.) 3*s*. 6*d*. net.

THE author has succeeded in presenting a brie but very useful and readable guide to succes in the formation and management of pastures, o rather, leys. The ley is of vital importance in Britai to-day, from the points of view both of the natio and of the individual farmer, who should aim a maintaining the fertility of his land, while producin at a high level, and making satisfactory profits. Th author lays emphasis on the factor of fertility. B proper manuring, cultivation, and the use of suitabl seeds mixtures, highly productive swards are obtained which maintain a large head of stock, which, in turn produce a well-dunged and urinated sod; when thi is ploughed, heavy arable crops result. Such i rotational farming, which is the only true basis o successful agriculture in Britain.

The author discusses how success can be achieve at each stage, beginning with the preparation of th land for the seeds mixture, and ending with th management of the sward by correct grazing. Usefu chapters are given on the selection of seed of th right strains, on the time to sow, and whether to us nurse crops; and the book ends with a useful list o seeds mixture prescriptions for leys of various duration and classes of soil.

The book is very practical, and combines th valuable experience of the scientific man wit that of a commercial man who was prepared t stake his career on the soundness of his advice. I is, perhaps, unusual to direct attention to a writer' experience, but the fact that the author set up i business as a 'consulting agrostologist'—the firs business of its kind in the world—adds greatly t the value and interest of this book.

DARWINIAN EXHIBITION IN MOSCOW

By SIR ARTHUR KEITH, F.R.S.

I HAVE had the privilege of reading a series of messages cabled by Mikhail Petrov to the president of the Linnean Society in which a description is given of an exhibition now displayed in the Zoological Museum, Moscow, to illustrate phases in the life and work of Charles Darwin. The exhibition, which has been organized by Prof. Turov, director of the Museum, and his staff, is on a scale beyond anything ever attempted in Great Britain or in any other country; in the words of M. Petrov, it "symbolizes the ever-growing cultural relations of two friendly nations who are united in a struggle against Nazi barbarism".

The exhibition begins with illustrations of Darwin's home life in Shrewsbury; passes on to his life and work on board the *Beagle*; then there follows what may be described as an objective account of the evolution of Darwin's masterpiece—"On the Origin of Species". The structure and distribution of coral reefs receives the fullest treatment. These are only a few of the sections of this exhibition, which is designed to meet the needs of the public rather than of the expert and is evidence of the intimate place given to Darwin and his works in the cultural life of Russia. Nor is this taste for Darwinism an affair of the moment; in these pages (NATURE, April 23, 1932, p. 606) was recorded the signal honour done to Darwin's memory by the Soviet Government on April 19, 1932—the fiftieth anniversary of his death. That day "was declared a public holiday in the U.S.S.R." Is it not a strange thing that our aggressive enemy should have domesticated Shakespeare in Germany while our Russian ally has taken to her heart Darwin—so often and so wrongly accused of being an instigator of war? Tolstoy has won wide homage in English-speaking countries; we in Great Britain must bestir ourselves if his great merits are to receive the recognition that those of Darwin have met with in the U.S.S.R.

There is another aspect of the Moscow exhibition which deserves attention. The reception which the "Origin" was accorded by the leading men of science in Russia during 1861–64 is illustrated by extracts from their writings, and the influence of its teaching on leaders of thought and action is brought home by extracts from speeches. Marx and Engels, as is well known, were influenced by their study of the "Origin"; Lenin regarded Darwin as the man who "placed biology, for the first time, on a sound scientific footing". M. Stalin's verdict on Darwin, given in 1938, is of particular interest: "In its development, science can name a good many men who found courage and means to break old, and to create new conceptions and laws, despite all obstacles—despite everything . . . such as Galileo, Darwin and many others". The description which the Prime Minister gave of M. Stalin in Parliament on his recent return from the U.S.S.R. helps us to understand his verdict on Darwin. "Premier Stalin," said Mr. Churchill, "has a deep cool wisdom and a complete absence of illusion of any kind." May not this description be applied to Darwin? He daily searched the face of living Nature in order that he might have no illusions about the manner in which she dealt with living things.

The year 1842 was one of the most eventful in Darwin's life; our colleagues in the U.S.S.R. do well in marking its centenary. In January of that year he finished the manuscript of "Coral Reefs" and sent it off to the printers; in May he corrected the last proofs. His home was then 12 Upper Gower Street, which he entered when he married his cousin, Emma Wedgwood, in January 1839; in 1842 he had entered his thirty-fourth year, was the happy father of two children and had taken into his service Joseph Parslow, who was to remain a member of the family for forty years. Darwin was then in a wretched state of health; his brain was continually overworking itself; he hated London; he called it "smokey", "dirty" and "odious"; he was "house-hunting", hoping to find a peaceful spot in the country within twenty miles of London. It was in the summer of 1842, while on a visit to Maer and to Shrewsbury, that "I allowed myself to speculate on the subject [the origin of species] and drew up some short notes". It is true he had been collecting facts which might throw light on the problem ever since he finished his "Journal" in July 1837; but this pencil sketch, drawn up in the summer of 1842, was his first attempt to apply the theory of natural selection to the explanation of his facts. We may, therefore, regard the year 1842 as marking the birth of the "Origin of Species".

On returning to London, house-hunting was taken up in earnest, the choice finally falling on Down House, in the parish of Downe, Kent, "16 miles from St. Pauls". The purchase had two advantages—rurality and price. Down House, standing on eighteen acres of ground, cost £2,200—£1,000 less than any other place then available at this time. Darwin's income was well over £1,000 per annum, but he feared 'extravagance' above all things; he was a great naturalist, but when answering the queries put to him by his cousin, Francis Galton, in 1873, it was his business ability, not his aptitude for scientific inquiry, to which he gave prominence. Thus it came about that the Darwin household was moved from London to Kent, the flitting taking place on September 14, 1842—another reason for marking the present year as a Darwinian centenary. On entering his new and permanent home he set to work on Part 2, of the "Geological Report of the Voyage of the *Beagle* (Volcanic Islands)" and published a pioneer contribution to glacial action in Britain—"Effects produced by the Ancient Glaciers of Caernarvonshire". He was also busy with plans for improving Down House. Clearly, 1842 was a notable year in the life of Charles Darwin.

Early life at Down House was overcast by a tragedy in the Darwin family. Nine days after arrival Mrs. Darwin was delivered of her third child, which lived only three weeks. There is in the archives of Down House—which, thanks to the public spirit of Sir Buckston Browne, is now preserved as a national memorial—a letter written by Darwin soon after the birth of this child. The letter is addressed to Mrs. Horner, wife of Darwin's geological friend Leonard Horner. Its opening sentences are worthy of quotation because of the light thrown on the opening month in the parish of Downe.

"I am much obliged for your letter and most kind congratulations. . . . We are going on very well and Emma [Mrs. Darwin] is making a quicker recovery owing, I think, to country air, than she has ever done before. Our children are very well and Willy [eldest son, then nearly four years of age] approves of 'country House' very much. I think the place will suit us very well. We have found moving so expensive that I have not ceased to be thankful that we bought a very cheap house. It is the quietest country I ever lived in."

In this and in other letters of this period, Darwin gives glimpses of his new surroundings—of nightingales, of larks, of fields pink with sainfoin, others white with spread chalk. It may interest our Russian colleagues to know that within these last ten years larks have moved away from the Down House fields, nightingales have almost forsaken its orchard and its sheltering trees, the pink and white fields have taken on other colours, and the sky, so peaceful a century ago, now resounds to the beat of propeller blades—sounds which we counted a nuisance in peacetime but which now, in these days, fall as a comforting music on our ears. But for the courage which makes this music, Down House might well have suffered the sad fate which, in spite of the splendid fighting of the Russians, has overtaken Tolstoy's old home.

To return for a moment to the Darwin exhibition in Moscow. We are glad to note the prominence which Prof. Turov has given to the spirit of humanitarianism which was so deeply ingrained in Darwin's nature—his hatred of cruelty and his horror of slavery. His indictment of slavery is illustrated by a quotation : "What an honour it is for England to be the first of European Nations to completely abolish slavery". This sentence is apparently taken from a letter which Darwin wrote from the Rio Plata and, addressed to his elder sister Caroline on May 22, 1833 ("Life and Letters", vol. 1, p. 246). He tells his sister that "it is impossible to see a negro and not feel kindly towards him" and that he is "watching the results of the election", then taking place at home. "What a proud thing for England," he exclaims, "if she is the first European nation which utterly abolishes it [slavery]". Britain was the first, for in that same year Parliament abolished slavery in all British colonies and spent 20 millions of pounds in compensating the slave owners. His hot condemnation of Captain Fitzroy's defence of slavery very nearly brought his career of naturalist on board the *Beagle* to a premature end. Even Sir Charles Lyell, for whom he had an unbounded admiration and affection, was sharply and hotly reprimanded when in 1845 he wrote equivocally of an institution which Darwin felt to be criminal. Even in his books, particularly in the "Descent of Man" (the edition in front of me is Murray's reprint of the second edition, 1913), we see his humanitarianism influencing his scientific verdicts. For example, when discussing the preservation of the weak and unfit by civilized nations, he writes (p. 206): "Nor could we check our sympathy, even at the urging of hard reasoning, without deterioration in the noblest part of our nature". He believed that, in the struggle between our higher and lower impulses, "virtue will be triumphant" (p. 192). After describing the prolonged travail which has divided mankind into so many diverse races, he seems to welcome a movement which would undo Nature's evolutionary scheme. Here is an extract from the chapter which deals with the rise of "Man's Moral Sense" (p. 187) :

"As man advances in civilization, and small tribes are united into larger communities, the simplest reason would tell each individual that he ought to extend his social instincts and sympathies to all members of the same nation . . . there is only an artificial barrier to prevent his sympathies extending to the men of all nations and races."

Those who, like Mr. H. G. Wells, advocate 'Universalism' as a remedy from the evils from which we now suffer—particularly the scourge of war—may, on the strength of this passage, claim the support of Charles Darwin. But then, on p. 219, we find this statement : "As man suffers from the same physical evils as the lower animals, he *has no right* to expect an immunity from the evils consequent on the struggle for existence. Had he not been subjected during primeval times to natural selection, assuredly he would never have attained to his present rank". From the context of this passage, one infers that Darwin expected that man's evolutionary struggle was to continue.

There is, I admit, a grave fault in Darwin's presentation of his facts in the "Descent of Man". In the last sentence just quoted we see the emphasis which Darwin places on the agency of natural selection in the evolution of man—an emphasis which has so misled many modern men of letters. Darwin gives prominence to competition, selection, survival, extermination, to all man's antagonistic qualities ; but when we look into the contents of his longest three chapters—3, 4 and 5—we find they are devoted to the evolution of man's co-operative mentality—the evolution of those instinctive and emotional reactions which bind men into family groups, into independent tribes—which are but extended families, and sovereign nations—which are but overgrown tribes. In the evolution of man co-operation has played quite as important a part as antagonism. Darwin assumed that men—even in their prehuman state—lived in social groups, and all that has been learned in the last seventy years justifies this assumption; and that the instinctive and emotional reactions which bound them into isolated groups had been developed from those more primitive ties which unite members of a human family.

The main struggle in the evolution of man, therefore, was between tribe and tribe, and it was this competitive aspect of the problem which seized Darwin's attention. I could cite many passages to prove that he was equally alive to the co-operative machinery which was at work inside each evolving tribe. For example (p. 203), "a high standard of morality gives but a slight or no advantage to each individual man and his children over other men of the same tribe, yet an increase in the number of well-endowed men and an advancement in the standard of morality will certainly give an immense advantage to one tribe over another". Without morality there could be no co-operation of members of a tribe. In reply to a criticism which the late Lord Morley passed on the "Descent of Man" Darwin gave this answer : "I have endeavoured to show how the struggle for existence between tribe and tribe depends on an advance in the moral and intellectual qualities of the members and not merely on their capacity of obtaining food" ("More Letters", vol. 1, p. 326). In brief, if we could have looked inside the developing brain of an early tribesman we should have found a dual mechanism at work, one giving rise to mental qualities which induced co-operation in members of a tribal team and another which impelled these members to maintain their team intact at all costs.

Light is thrown on the difficult problem of combining co-operation with competition in a corporate body (for a primitive tribe is a close corporation of interbreeding individuals) by what is taking place in the modern business world. We may take our illustration from our banking businesses. Ever since Darwin's day there has been taking place, just as happened in recent millennia in the human world, a tendency to the creation of an ever-increasing size of the evolutionary units; local banks have been amalgamated, and local amalgamations have been swallowed by central concerns, so that now only a limited number of great competing units survive, which units we may compare to the great nations of to-day. These large corporations, being managed by self-electing directorates, are run, as a recent writer points out (*The Times*, "Private Enterprise", September 18 and 19, 1942), for the benefit not of the whole British community but for a section of it. The problem is how the whole community can be benefited and yet be free from the evils, or risks, of monopoly.

Nature had, and has, to face the same problem in the evolution of mankind. The directorate she instituted for her purpose is that combination of qualities we call 'human nature', in which co-operative and competitive inborn or instinctive tendencies work for the good of the community or tribe as a whole. To quote Darwin once more (p. 190), "The social instincts . . . no doubt were acquired by man, as by the lower animals for the good of the community".

THE EXPLOITATION OF MINERALS IN RELATION TO NATIONAL AND WORLD PLANNING*

By DR. L. DUDLEY STAMP

ALL minerals are won by what used to be called 'robber economy'. Man has no control over the location of minerals: his efforts are directed towards the discovery and subsequent winning of deposits the position of which is dependent upon the geological structure of the earth, or towards the utilization of deposits not previously regarded as 'economic'. Once any given deposit is exhausted it is not replenished.

Thus the social and economic consequences of the extractive industries are entirely different from those which result from industries connected with either the animal or vegetable kingdoms. In those cases, provided adequate care is taken, Nature replenishes the stores year by year and the dependent industries are afforded a marked degree of permanence. By the limited nature of the resources on which they depend, mineral industries, whether merely extraction or processing, or secondary industries based thereon, are essentially impermanent.

It is of considerable importance to distinguish between two groups of economic minerals. In the first place, there are those which occur in limited supply and where the object of mining is to remove *all*, or as much as is economically feasible, of the mineral. Into this category come oil, coal, iron ore (at least above a certain metal content), and most metalliferous ores. In the second place, there are those minerals which occur in such abundance that only parts of the available deposits are ever likely to be worked. Into this category come limestone (including chalk) for lime and cement, clay for bricks and tiles, slate, building-stones, road metal, sand and gravel.

In the international planning of mineral exploitation it is the first group which is concerned: the rocks and minerals of the second group are of the greatest importance, but nationally rather than internationally. In the minerals of the first group there is little choice in the siting of the works; in the minerals of the second group it is possible to plan the actual areas of working to a considerable extent—they are usually dictated primarily on economic grounds, especially in relation to transport costs, but where necessary may be planned in accordance with requirements of the national planning or the location of industry, the conservation of agricultural land, the preservation of amenities and other relevant factors.

Restricting attention to the minerals of the first group, those of which the object is to remove the whole or as much as possible, a definite cycle is associated with the working. This is, briefly, exploration, exploitation and exhaustion. With *exploration* and the early stages of exploitation comes a very rapid development, an influx of population, a spate of building and often of extravagant expenditure—indeed all the conditions associated with a 'mining boom' whether it be a gold rush, an oil boom, or simply the development of a new coalfield. The period of relatively steady *exploitation* may be short (as in the case of alluvial gold or tin) or it may be long—even running into a century or more (as in the case of a coalfield). If it is long, then social and economic conditions become stabilized, substantial towns are built and the whole community may go so far as to forget that its existence is primarily dependent on the exploitation of a mineral deposit. This is the position reached in many of the older coalfields of Britain. The period of *exhaustion* or approaching exhaustion is one of serious and inevitable maladjustments often resulting in much human suffering and misery, and which calls for careful thought and action—it cannot be left to right itself.

Thus the recognition of the right of the nations of the world to share the world's mineral resources carries with it the obligation of those nations to accept responsibility and to share the burden of whatever social and economic readjustments may be needed. There is, in other words, an obligation to safeguard the interests of human beings both during and after the exploitation of the minerals.

Most of the problems which arise, and some of the readjustments, can be illustrated, though on a small scale, in the British Isles.

(*a*) Tin has been won in Cornwall and the south-west since pre-Roman times. Exploitation reached its peak some seventy years ago and resulted in a large number of mines with their conspicuous pithead gear widely scattered over the wilder parts of the county. At least two not inconsiderable towns, Camborne and Redruth, grew up dependent primarily on mining. To-day most of the deposits are sufficiently near exhaustion that in pre-war years their exploitation had become uneconomic. As a mine approaches the later stage of its career, there is little money left after running costs have been met and, when the mine fails, none at all to remove the old gear and buildings, which thus become unsightly ruins marring the countryside. In the case of the Cornish tin mines, much of the skill, experience and capital released from local mines was transferred abroad—many Malayan companies are offshoots of Cornish parents and are often staffed by Cornish miners. Camborne and Redruth came to depend on foreign investments —one solution, perhaps a rare one, of this difficult problem.

---

* Paper read at the Conference on Mineral Resources and the Atlantic Charter arranged by the Division for the Social and International Relations of Science of the British Association on July 25.

(*b*) Lead was won by the Romans and at this moment is being worked again in Cumbria and elsewhere. The position is much as with tin, except that there is here an additional complication: that of noxious effluents and poisonous fumes from smelting. The first promise often to destroy freshwater life, including valuable fisheries; the second may ruin agriculture as well as natural vegetation for miles round. The aftermath is terrible. The same is true of the extraction of salt, gypsum, and the associated heavy chemical industries.

(*c*) Iron ore. The once flourishing iron industry of the Weald has gone, leaving little or no trace; the iron industry of the South Wales coalfield is more recent and has left behind a solid core, in peace-time conditions at least, of unemployment. In the Black Country, the evils have been mitigated by the switch over to other industries. The latest phase of maladjustment in the iron industry is seen in Northamptonshire, where thousands of acres of good agricultural land are being left, after removal of the ore, a stony desert of steep ridges and valleys useless to man and beast and affording little hope even for useful vegetation or afforestation. Yet a limited expenditure, with the aid of modern levelling machinery of the type now being used on aerodromes, could restore this land to usefulness.

(*d*) Slate quarries, chalk quarries, and other scattered surface workings, including those for gravel and sand, raise especially questions of amenity and the need for regulation, including definite directions towards the location of industry, in national planning.

(*e*) Coalfields afford examples of the problems raised by mineral working at their most difficult. A coalfield develops slowly, and its development gives rise to such permanent towns and villages that the subsequent problems of readjustment are extremely difficult. So rooted are the human beings that the solution of the problem has tended to be, not the 'scrapping' of the settlements—which is the logical course—and the removal of the people, but the deliberate effort to bring industry of new types to the pool of labour thus available.

These examples, drawn from Britain, are sufficient to illustrate the far-reaching character of the human and economic problems raised by the apparently simple proposition of sharing the world's mineral resources. It would seem that three principles emerge:

(1) Mineral exploitation inevitably results in a need for restoration, whether it be of land or of the social structure of the community.

(2) This restoration should be obligatory on those, whether nations or individuals, who derive benefit from the working of the minerals.

(3) In the latter stages of mineral exploitation there is never a surplus of money, and therefore there should be some provision, comparable to an amortization insurance, made when the industry is flourishing, for use in the later stages for the work of restoration and rehabilitation.

A STUDY OF ACCIDENTS

EMERGENCY REPORT No. 3 of the Industrial Health Research Board* is concerned with the problem of accidents, always important but still more so in war-time, when many circumstances combine to increase the risk of accidents. There is a tendency on the part of many people to accept accidents as inevitable happenings; one has only to recall the indifference to road accidents before the War to realize this. For some time now, efforts have been made to render the environment in which the industrial worker spends his working time safer; the legal aspect is embodied in the Factories Act and the Ministry of Labour Regulations, while advice is given by factory inspectors and the Royal Society for the Prevention of Accidents.

The report on accidents falls into two parts: the first part concerns itself with the general factors likely to affect all workers in different degrees; the second part deals with the individual differences which result in reactions which are not uniform.

General Factors affecting the Incidence of Accidents

(1) *Hours of work.* During the War of 1914–18 investigations showed that unduly long hours led to an increase in the accident-rate, and there is evidence that fatigue was largely responsible. In war-time longer working hours are necessary, but there comes a point past which it is no longer profitable to let people work. Fatigue not only reduces the speed and accuracy of muscular movements, but also affects mental alertness.

(2) *Heating and ventilation.* The number of cuts and minor accidents increases with temperatures much above or below the range of 65–69° F. Where processes generate much radiant heat the worker should be protected. Adequate ventilation should not be regarded merely as a side issue.

(3) *Lighting.* Lighting so inadequate that the worker cannot see his work effectively is a contributory cause of accidents. Too great a variation in lighting must also be avoided. Natural lighting, that is, daylight, is ideal when there is enough of it.

(4) *Speed.* Speed of production is a frequent cause of accidents, and since it is necessary in modern industry, care must be taken that machines are not moving too quickly, nor workers put on to speeds to which they cannot adjust themselves.

(5) *Inexperience and age.* Both these conditions are related to accidents, but are independent. People, whatever may be their age, if inexperienced at industrial work, are known to have a higher accident-rate than a similar group of experienced workers. Also young people, whether experienced or not, are more liable to have accidents than older people, partly because they are less responsible and partly because they have less control over their muscles. Therefore there should be adequate training for beginners, whether young or not, and adequate supervision for the young.

(6) *Fitness for the work.* Quite apart from physical unfitness a worker may be mentally ill-adapted to his work. There is evidence that workers of high mental ability, if employed on repetitive work demanding little thought, become bored, which state

---

* The Personal Factor in Accidents. Emergency Report No. 3. Industrial Health Research Board. 1942. 4*d*. net.

leads to a variable output, fatigue and therefore to a high accident rate. This question of fitness is connected with that of vocational selection, to which far too little attention is paid.

(7) *Attitude of management and workers.* Both management and the workers have a part to play in accident prevention. If the former takes up the attitude that accident prevention is not an essential part of production, then there is little likelihood of a serious reduction even though lip service be paid to safety committees.

On the other hand, even proficient workers often neglect to take safety precautions because each works on the very human principle of "It can't happen to me". Although a worker may be very proficient, that does not connote an immunity to accidents ; a temporary lack of thought due perhaps to slight physical ill-health or mental pre-occupation may have serious consequences. Also the expert workers have a responsibility for the less expert, since these, particularly if young, tend to imitate the former. Care is not synonymous with fear.

Accident-proneness

When all the above causes have been considered there yet remains a factor that has been dimly recognized but until recently ignored. Everyday experience or the examination of accident statistics makes it clear that, given similar conditions of environment, or of the other factors already mentioned, there are people who have more accidents than their fellows. This difference is attributed by some to chance or to the effect of a first accident on a person's liability to another. Scientific analysis has, however, shown the special importance of a condition which is now known as 'accident-proneness'.

Statistical workers were the first to study systematically the unequal distribution of accidents among people exposed to the same risks. It is obvious that the accidents studied have been chiefly minor ones, since fortunately major accidents are not sufficiently frequent during a reasonable period of observation. Where, however, it has been possible to relate major accidents with minor ones, it has been found that those who had many of the latter also had an undue number of the former. Efforts made, therefore, to prevent people specially susceptible to accidents from dangerous work will protect them both from major and minor accidents.

Accident-proneness must be distinguished from accident liability. Liability to accident is largely determined by the degree of risk to which a person is exposed. Differing environmental conditions alter accident liability quite apart from any personal characteristics predisposing towards accidents. Although general liability differs from one group of workers to another according to the nature of their occupation and working conditions, yet in any one group of workers, however great or small may be the risk, some have more than their fair share of the accidents.

Psychological investigations have shown that those with an unduly high accident rate can be partly differentiated on the basis of measurable individual reactions.

So far only one factor of this accident-proneness has been identified and measured ; others may eventually be measured ; some may never be. For nearly twenty years investigators have been experimenting to find some test or group of tests to serve as a means of predicting this minority. Tests used to measure the capacity to respond accurately within a controlled time interval to various sensory stimuli have given reliable results in the case of skilled workers. In skilled occupations those who do well in the tests have been found to have, not only a lower accident rate, but also a higher rate of proficiency than those who do badly. Unfortunately, the tests cannot select all the accident-prone, though they do select a fair proportion.

There is no question of not employing the accident-prone ; they are perfectly normal people who can be usefully employed in most occupations, but if employed in an occupation with a high accident liability they are a danger to themselves and to others.

Accident liability is the sum total of all the factors determining accident incidence ; accident-proneness refers solely to the individual factors affecting it.

There are two ways of partially predicting the accident-prone. One is by finding the number of accidents sustained by each individual in a working group during a previous period of exposure ; the other by using certain tests. The most effective way is to combine both methods. This procedure has been shown in both transport and industrial accidents to reduce the subsequent accident rate to an appreciable extent.

It must be emphasized that if proper use is to be made of our knowledge it is most important that adequate records should be kept. Quite apart from the humanitarian aspect of accident prevention, a reduction in the working time lost would have a beneficial effect on production. MAY SMITH.

OBITUARIES

Dr. S. G. Barker, O.B.E.

THE world of fibres in its industrial development lost an outstanding personality and one of its greatest authorities in the sudden death, on August 28 last, of Dr. Sydney George Barker, scientific adviser to the Indian Jute Mills Association since 1934. Prior to taking up this appointment, the late Dr. Barker had been director of the Wool Industries Research Association, and most of his scientific and business life during the last twenty years was occupied in conducting and controlling investigations into the sources, preparation, properties and commercial utilization of the scarcer—principally hard—fibres.

Dr. Barker was born in York in 1887, of typical Yorkshire Nonconformist stock, and, throughout his life, he displayed all the sterling qualities and rugged honesty of character and purpose of his origin and upbringing. His early education in York was followed by study—principally of physics and mathematics—at the Imperial College of Science and Technology, London, and at the University of Berlin. He was one of the early holders of the research scholarships, tenable in German universities, instituted as a result of the efforts of the late King Edward VII to bring about a closer understanding between the two countries. Academically, although he won a number of distinctions, his progress was marked more by the steady and sustained effort of his acutely critical and inquiring mind than by any brilliant scholastic achievements.

In 1915, Dr. Barker began that long connexion with India and Indian industries which was to continue until the close of his life. He became director of industries to the Government of Travancore and produced for that Government a monumental "Survey" of the industrial possibilities of the province.

His sound judgment and acute perception of essentials in technological and industrial matters led to many calls upon him by various Indian Provincial Governments, and his work for these is embodied in more than fifty bulletins and papers on chemical and allied industries for State Departments and other official bodies. Dr. Barker, with his wife, whom he had married in 1915 before he sailed from England, threw himself wholeheartedly into all the activities of his surroundings, and served for some time as an officer of one of the local regiments. He was, for a period, vice-principal of the Maharajah's College at Trivandrum (University of Madras) and took an active part in its development.

In 1921, a breakdown in health forced Barker to return to England, and he began to suffer from the deafness which, in later years, became a severe handicap to all his activities. On his arrival in this country, he served for a time as principal assistant in the Research Department of Woolwich Arsenal. In 1926, he took up what was to be one of the great successes of his career—the directorship of the Wool Industries Research Association in Leeds. His brilliant work in this post, his devising of new processes and improvement in old ones, his invention of instruments and methods of testing, his work in organizing and compacting manufacture, resulted in notable progress in this fundamental industry, and established the Association as an indispensable factor in the development of sheep breeding and rearing and the improvement of the quality of the wool fibre throughout the British Empire. During this period also he worked in the closest association with and for the (now defunct) Empire Marketing Board, for which he examined many possibilities in the utilization of various fibres produced in different parts of the Empire. For this work he was awarded the O.B.E.

In 1934 he was invited to act as scientific adviser to the Indian Jute Mills Association, a position which he held to the time of his death. He visited India in 1935 and again in 1938 to establish and extend laboratories and supervise research and development schemes on behalf of the jute industry, and, on his return, he set up similar laboratories in Great Britain, supplementing and controlling the work in Calcutta. In this industry, as in the case of wool, he was responsible for rapid and useful progress, until the outbreak of war gave an already busy life still more work to be undertaken. He was appointed to various official advisory posts chiefly connected with the use of textiles and fibres in the war effort, and he was never lacking in suggestion and in the organization of inquiry whenever problems were encountered in which these products could be of use. His increased work caused him to suffer still more from deafness and from general ill-health until, in the course of completing an official journey to the north, he collapsed and shortly thereafter passed away.

Dr. Barker was a prodigious worker with an extraordinary memory for unusual items of information likely to be of use in his researches, and an energetic, cheerful and loyal colleague. He covered a wider range of scientific and industrial investigation during his life than is given to most men to achieve, and his success in what he undertook was recognized by the many honours conferred upon him and by membership of a large number of scientific and technical societies and committees, both at home and abroad. His output of written contributions to knowledge includes two monumental works on "Wool", and treatises on "Coir", "Sisal" and "Jute", in all of which fibres he was the world's foremost authority. Besides these works, he has to his name more than two hundred shorter papers, brochures and reviews of a less comprehensive character.

His death at this time, when his knowledge and experience were of so much value to the national war effort, is a grievous loss, and the thought that his passing was due solely to the intensity of his striving to help, is a tragedy. He leaves a widow, but no family.

Prof. Ludwig Aschoff

Prof. Ludwig Aschoff, the eminent German pathologist and medical historian, whose death at Freiburg im Breisgau was recently announced, was born in Berlin on January 10, 1866. He received his medical education at Bonn, Strassburg and Berlin and qualified at Bonn in 1889. After serving as assistant in Recklinghausen's Pathological Institute during 1891–1893 and at the pathological institute at Göttingen from 1893 until 1903, he was appointed professor of morbid anatomy at Marburg and at Freiburg im Breisgau three years later. His principal work was a system of morbid anatomy, of which he was editor and to which he contributed the articles on disorders of the circulation, inflammation, the heart and pericardium, urinary system, female sexual apparatus, and the digestive system. The eighth edition appeared in 1936. His other publications included works on appendicitis, cholelithiasis, thrombosis, scurvy, and a history of medicine in tabular form, of which the third edition in collaboration with Prof. Paul Diepgen was published in 1936. He was also editor of *Beiträge zur pathologischen Anatomie und zur allgemeinen Pathologie* and co-editor of *Veröffentlichungen aus der (Kriegs-) Gewerbe- und Konstitutionspathologie*. Aschoff's name is attached to an organ in the paradidymis and paroophoron, rheumatic nodules in the myocardium and lungs and with that of Tawara to the atrioventricular node in the heart. J. D. Rolleston.

We regret to announce the following deaths:

Mr. F. W. Clifford, librarian of the Chemical Society, on September 21.

Prof. E. Fawcett, emeritus professor of anatomy in the University of Bristol, on September 22, aged seventy-five.

Prof. P. A. Hillhouse, professor of naval architecture in the University of Glasgow since 1921, on September 28, aged seventy-three.

Prof. W. J. G. Land, emeritus professor of botany in the University of Chicago, known for his work on tropical plants, on August 1, aged seventy-six.

Dr. Henry G. Knight, chief of the Bureau of Chemistry and Soils of the U.S. Department of Agriculture, on July 13, aged sixty-three.

Prof. David Waterston, Bute professor of anatomy in the University of St. Andrews, on September 4, aged seventy-one.

Prof. H. D. Wright, professor of bacteriology in the University of Liverpool and City bacteriologist to the Liverpool Corporation, on September 9, aged fifty-one.

NEWS and VIEWS

The Church as a Social Force

THE mass meeting held at the Albert Hall, London, on September 26, was convincing evidence of the keen interest that is shown in the Church as a social force, especially in view of the fact that many times more applications for tickets were made than the huge hall could accommodate. The Archbishops of Canterbury and York and the Lord Privy Seal were supported by ambassadors, bishops and representatives of various religious bodies, commerce and industry at this meeting, which was arranged and organized by the Industrial Christian Fellowship as a sequel to the Malvern Conference of 1941. The Archbishop of Canterbury, who has shown a keen interest in, and done splendid work for, the social life of the country, and has already made valuable suggestions towards social reconstruction, emphasized that the Church has both a right and a duty towards declaring and supporting those principles which should govern the order of society. This is, after all, the natural sequence to the universally recognized duty of the Church to lay down principles for the conduct of individuals, the only difference being that the Church should now extend her influence to society, that is, groups of individuals. In the past, by ignoring society, fellowship has either not been fostered or has been broken where it existed, thus resulting in gross disparity of wealth and poverty, lack of leisure and so forth. The predominant motive guiding enterprise in the past has been that of profit. In the future, this must be put in its proper place, for it is not only an expression of selfishness but is also clearly not in the general interest. For the promotion of the general welfare there are two special problems, namely, land and money. The traditional Christian principle still holds good, that the right of property was a right of stewardship—never exclusive use. Therefore the Uthwatt Report, which aims at the combination of the advantage of public ownership and ultimate control with private initiative, is to be welcomed. So far as money is concerned, banks, now more or less amalgamated, should be limited in power to the amount deposited by their clients, while the issue of new credit should be a function of public authority.

The Archbishop of York spoke on housing and planning, stressing that a gigantic urban housing programme will have to be organized as soon as hostilities cease. The problem, however, already exists, both in town and country, and if there is any hope of demobilized men settling down to life in the country then steps should be taken to provide houses in rural districts even during the War. But housing must be planned. In this connexion we have as an example the disastrous mistakes made after the War of 1914–18. Further growth of already overgrown towns must be discouraged, while the decentralization and dispersal of new industries must be encouraged. New towns must be real communities centred round church, school and guildhall. Agricultural land and national parks must be earmarked, and, if necessary, private interests overruled.

Sir Stafford Cripps emphasized the recent enormous growth of the social conscience of the churches. So now it is for the Church to provide the moral force and the driving power for social and economic developments. The Church might well adopt as its Christian objectives the five "simple desires of the people of America" as expressed by President Roosevelt, namely: equality of opportunity; jobs for those who can work; security; ending of privileges for the few; preservation of civil liberties for all. If the Church agrees that these objectives are the embodiment of fundamental Christian principles, then nothing should stand in the way of their realization. Sir Stafford suggested that perhaps the Church herself is standing in the way; for example, if privilege is to be ended, then the Church herself must be prepared to give up her privileges with the rest, not excluding the privilege of endowment and of establishment.

The Bishop of Bristol gave an account of the growth and activities of the Industrial Christian Fellowship, and Miss Knight-Bruce spoke on "Education in the New Order". The substance of all the addresses given at the meeting is contained in a pamphlet entitled "The Church Looks Forward", published by the Industrial Christian Fellowship, 1 Broadway, Westminster, S.W.1, price 6*d*. It is hoped to discuss this pamphlet at greater length in NATURE shortly.

Natural Sources of Rubber

AN interesting note on possible West African sources of rubber is contributed to *Farm and Forest* (3, No. 2, June 1942) by J. H. Mackay, the general editor, who is on the staff of the Forest Department, Nigeria. Latexes vary in the proportion of resin and caoutchouc they contain, the more resinous providing the bird limes of the West African native. 'Ate', the coagulated latex of the vine *Carpodinus hirsuta*, has been in demand since the outbreak of war for trapping moth pests of stored cocoa, but it was formerly exported as a 'paste' rubber. The latex of *Ficus platyphylla* yields the Niger gutta of commerce; for this a former demand for use in the manufacture of chewing gum shows signs of reviving. It contains some 13 per cent caoutchouc. *Funtumia elastica* is the only indigenous rubber yielding tree; in 1896 some three thousand tons of rubber was exported from it but the yield fell owing to ruthless tapping.

Various lianes of the same family (Apocynaceæ) also yield excellent rubber. In cultivation the yield of rubber from Funtumia was only about 60 lb. of dry rubber to the acre compared with several hundred pounds from Hevea. *Hevea brasiliensis* was introduced into Lagos in 1894 and in 1938 exports from the Cameroons and Nigeria exceeded three thousand tons. The Benin Sands have proved particularly suitable for its cultivation. A recent publication by Muriel E. Whalley (*Nat. Res. Council*, No. 1071, Ottawa, 1942) may be of general use in connexion with the present widespread survey of possible natural sources of rubber. It surveys the various methods of extracting rubber from plants as recorded in the literature.

Control of Lantana in Madras

THE control of Lantana (*Lantana aculeata* = *L. camara*) and the spike disease of sandal have been occupying the attention of the forest officer in parts of the Madras Presidency for half a century. The Lantana was first introduced into India from Ceylon (it is a native of Central America) in 1833 as a garden plant. Its spread through peninsular India was almost meteoric and it has become naturalized throughout the whole country. Its importance as a forest pest was first voiced in 1893, and since that period many attempts, mostly abortive, have been made to deal with it. From 1934 research work with chemical methods has been carried out. These investigations were at first published in the *Indian Forester* but are now reproduced with the figures in "The Control of Lantana by a Sodium Chlorate Spray", by A. L. Griffith, sylviculturist, Forest Research Institute, Dehra Dun (*For. Bull.*, No. 106, Sylvicultural Series, Govt. of India Press, Calcutta, 1941). The importance of the investigations will be evident by the rapidity of the spread of the pest. In north Salem, where the work has been undertaken, it is recorded that in the north Salem forest division in 1917 there were 4,800 acres of Lantana. In 1935 the area had increased to 56,000 acres, while in 1941 it is stated that a very recent estimate put the area at just over 100,000 acres. This was the area in Government Reserved Forest only in the district. The density of the Lantana is often as much as 5,000 to 10,000 stems per acre. The experience gained so far shows that successful control by spraying with sodium chlorate is possible at a cost roughly of £10 per acre and that such a spray has no toxic effect on subsequent rejuvenation on the area. The results of this piece of research appear to be important. The Bulletin gives full details of the methods of applying the spray.

Psychiatry and Alcoholism

In a recent paper (*Virginia Med. Monthly*, 69, 417; 1942), Dr. Merrill Moore, associate in psychiatry at the Harvard Medical School and director of research at the Washington Hospital for the Treatment and Prevention of Alcoholism, declares that the three greatest public health problems in the United States to-day are tuberculosis, syphilis and alcoholism. Although the first two have received continuous attention from the medical profession during the last twenty years, alcoholism has not yet been completely accepted as a medical problem. According to Dr. Moore, acute or chronic alcoholism seems to result partly from the psychological inadequacy of the individual, and is therefore most likely to be found in persons who in childhood have been over-protected, too strongly dominated or pampered by over-solicitous parents. Prolonged drinking usually results in some form of neuropsychiatric disorder, which may be an avitaminosis, such as alcoholic neuritis, or pellagra caused by faulty diet, or there may be a frank alcoholic psychosis such as Korsakow's syndrome.

The frequent association of mental disease with alcoholism is shown by the fact that 60 per cent of all patients admitted to Massachusetts mental hospitals in the last twenty-five years gave a history of alcoholism. The high cost of alcoholism to the taxpayer is due to the fact that most alcoholic men and women are cared for in State or municipal hospitals to which they make no payment, and relief is required for the families and dependants of alcoholics whose income and earning power have been lost. Moreover, the cost is increased by the maintenance of courts for the distribution of drunkards in penal institutions. Dr. Moore maintains that there is a great need for the establishment of special clinics and hospital facilities for the treatment of alcoholics. At present they are not welcomed for treatment unless they can afford the necessarily high cost of private institutions, nor are they accepted at most State institutions unless they are suffering from alcoholic psychoses or equally severe mental illnesses in which alcoholism plays a secondary part.

The Journey of the Sun

Ralf E. Wilson discusses the motion of the sun in the Galaxy in Leaflet No. 161 (July, 1942) issued by the Astronomical Society of the Pacific. Before 1900, all determinations of the apex of the sun's motion were based upon proper motions, that is, motions at right angles to the line joining the star to the earth; and many of these were poorly determined and affected by appreciable systematic errors. About 1910, previous determinations were superseded by the results of two major investigations. The proper motions of about 6,000 stars had been determined on a standard system, and the observations started early in the century had produced 1,200 radial velocities. The latter gave an apex about 9° south of that derived from proper motions, and part of the discrepancy was attributed to the fact that radial velocities referred almost entirely to stars brighter than magnitude 5·5, the proper motions including essentially all stars brighter than magnitude 6 and many fainter ones. As radial velocities became available for the fainter stars the discordance increased, and in 1925 was largely removed by the discovery of systematic errors in the proper motions. The most recent investigations show that the motion of the sun, with respect to the naked-eye stars, is towards a point at right ascension 18h. and declination + 30°, near o Herculis, with a speed of 12 miles a second. The actual direction in which the sun is travelling in its galactic orbit lies about 40° north and east of the position just given, and the speed is about 180 miles a second. The low-velocity stars, with reference to which the sun's speed is 12 miles a second, are members of the same galactic subsystem as the sun, and are also subject to the same amount of rotation. The rotation of the sun around the centre of the galaxy is completed in about 200 million years.

New Companion to μ Draconis

Dr. K. Aa. Strand, of Sproul Observatory, has reported the existence of a third companion in the double-star system of μ Draconis (*Sky and Telescope*, August). It is known only by the regular fluctuations from the expected motion of the two visible components, observations having extended over three years. The brighter components have a period of revolution of about 1,500 years and the new companion revolves around one of them at a distance of about three astronomical units. It is a dwarf star with a mass half that of the sun.

Electricity in the Annealing of Glass

A paper by E. S. Morris on the application of electricity to the annealing of glass bottles and containers (*J. Inst. Elec. Eng.*, 89, Pt. 2, No. 10; Aug., 1942) first explains the nature and primary importance of annealing processes as applied to commercial glassware, with particular reference to bottles and containers. Development stages, from heated brick arches to portable and continuous lehrs, are then described in the section on mechanical improvements. The application of controlled heat to the fused and moulded product is shown through the transition stages of coal, producer-gas and oil firing, to complete electrification of annealing lehrs. Insulation factors and methods; heat conservation and re-application; cooling graduations; economic and product quality considerations in favouring the application of electricity as a power and heating element, are all made subjects for explanatory data. A brief account is given of tumbler-edge glazing and enamelling, which involve the processing of pre-annealed cold ware.

An A.C. and D.C. Peak-Factor Meter

E. H. W. Banner (*J. Inst. Elec. Eng.*, 89, Pt. 2, No. 10; Aug., 1942) describes an electrostatic voltmeter type of instrument connected to give readings proportional to the r.m.s. voltage and designed to give a rapid indication of the peak factor (peak/r.m.s.). When the reading is steady, operation of a press-key introduces a rectifier into the circuit for peak voltage, and in the case of alternating current also introduces by a tapping $1/\sqrt{2}$ times the applied voltage, so that the voltage applied to the voltmeter is the same as for the r.m.s. position if the wave form is sinusoidal. In this case no pointer movement occurs and the scale may be calibrated as for 1·41 peak factor. Other peak factors may be added directly from the voltage scale. The application to rectified and smoothed direct current is also proposed, 'pure' direct current having a peak factor of unity. It is further proposed that 'impure' direct current may be specified by its peak factor rather than by the 'ripple', as no standard is laid down for the term 'ripple'. Conditions of use are considered and possible errors examined. The instrument is inherently accurate, as the voltmeter scale is used for both peak and r.m.s. readings and scale errors thus tend to cancel out. Tests have borne out the theoretical considerations.

General Health and Dental Hygiene in Mexico

In a recent paper (*Bol. Of. San. Panamericana*, 21, 643; 1942) read before the Third Medico-Dental Convention at Mexico City, Dr. Miguel E. Bustamante discusses the development of public health dentistry in Mexico. At the present time the Department of Sanitary Specialization, which is maintained jointly by the Public Health Department and the International Health Division of the Rockefeller Foundation, provides free dental care by the supply of full-time dentists. There are dental services connected with the school health services in forty cities, and in the Federal District dental clinics in dispensaries of the Ministry of Public Assistance are open to adults. In 1940 there were 31 dentists working exclusively for the co-ordinated services of the various States, and the Public Health Welfare and Education Departments employ an even larger number in the Federal District. Within recent years dentists have collaborated with doctors, sanitary engineers, nurses and laboratory workers in the task of preventive medicine instead of confining themselves to the treatment of patients already suffering from infections of the mouth. The increased interest taken in dental hygiene is shown by the attention given to the patient's previous diseases, the chemical composition of his drinking water, the kind of food he eats and, in the case of children, the health condition of the parents, and the diet of the child from an early age. Prenatal hygiene followed by correct child nutrition and prevention of contagious diseases such as measles, whooping-cough and smallpox, greatly contribute to dental hygiene.

Radiotherapy in Peru

The July issue of the *Boletín de la Oficina Sanitaria Panamericana* gives an account of the Peruvian National Institute of Radiotherapy which was opened at Lima on September 19, 1940. It is devoted to the study and prevention of cancer and to the promotion of specialized university training on the subject. It will be provided with all the modern equipment for the early treatment of cancer and will supervise educational and social work directed against this disease. The institute occupies a modern building containing five stories, and is equipped with apparatus for X-ray diagnosis, X-ray therapy and general radiotherapy, as well as with a general physiotherapy department. There is a laboratory for hæmatology, serology and histopathology, as well as clinics for general medicine, surgery, gynæcology, urology, gastro-enterology, otorhinolaryngology, stomatology, etc. A hospital contains a hundred beds for free and paying patients, and the number of beds can be increased if necessary. One floor has been reserved for the technical staff and nurses. By the end of June 1941 the institute had treated 575 persons.

Recent Earthquake Records

According to preliminary bulletins just received from the Central Station of the Jesuit Seismological Association at St. Louis, U.S.A. (director, J. B. Macelwane, *S.J.*), fifteen strong earthquakes were registered on the seismograms during the first quarter of 1942. Further, two strong earthquakes were registered during the early part of April. On April 8, from the readings of seismograms obtained at twelve observatories, an earthquake with initial time near 15h. 40m. 10s. U.T. had its approximate epicentre at lat. 11° N., long. 118·8° E., which is in the China Sea, west of Bacuit (Palawan Island), north of Borneo. On April 11 the seismograms from eight observatories apparently indicated two deep-focus earthquakes in close succession and having nearby epicentres. The first had initial time near 01h. 25m. 23s. U.T. and epicentre near lat. 15·2° N., long. 91·5° W., with depth of focus about 230 km. The epicentres of the earthquakes were thus very close to the volcano Tajuulcom in Guatemala (Central America).

Use of Specialist Journals

The council of the Association of Special Libraries and Information Bureaux (ASLIB), 31 Museum Street, London, W.C.1, is offering to give advice on the disposal of specialist scientific and other journals. Many important libraries, not only in Great Britain but also in other countries, have been damaged or destroyed by enemy action, and in consequence it has become increasingly difficult to obtain back numbers of specialist periodicals for consultation; current issues have also gone astray from time to time through postal and similar difficulties. Yet in many cases, private individuals receive copies of scientific papers which they do not wish to keep for more than a limited period. The Association therefore suggests that, as a first step, members of professional and learned societies should return unwanted copies of papers they receive as part of their membership to their societies. The societies would in this way be able to build up stocks of their own publications against the time when damaged libraries will be endeavouring to build up their stocks.

Erratum. The last paragraph in the News and Views columns of Nature of September 26 (p. 372) referred to the opening meeting of the new session of the Institute of Fuel, not the Iron and Steel Institute as printed.

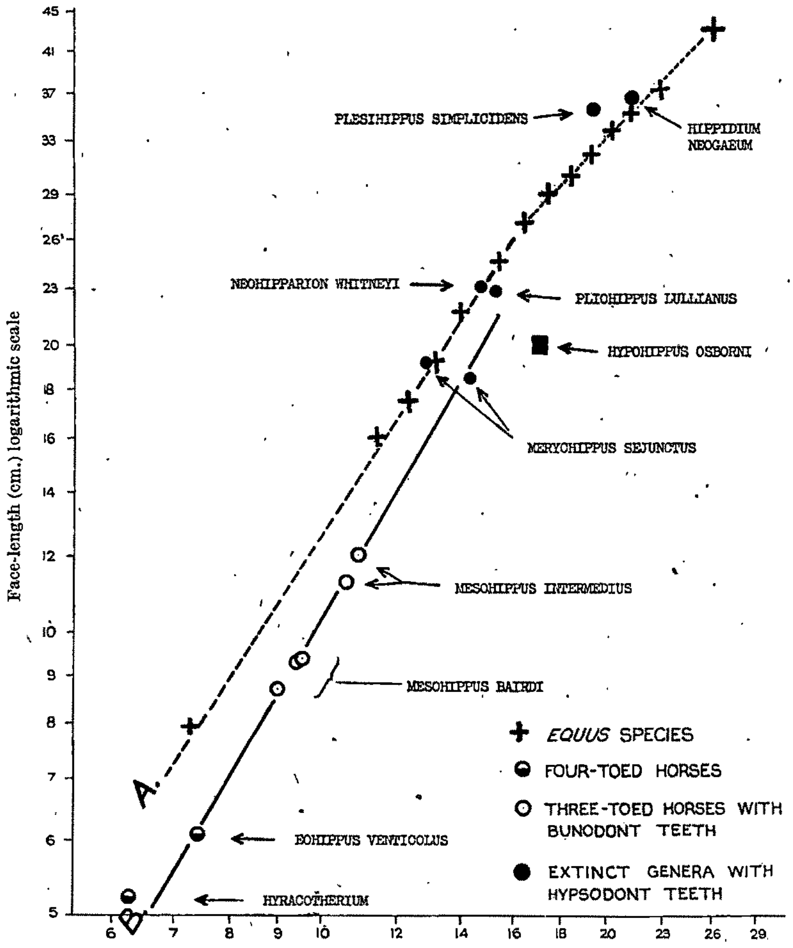
Evolution in the Horse's Skull

ROBB[1] claimed that evolutionary changes in the horse's facial index (face-length/cranium-length) could be explained on the basis of a single law of relative growth of the face against the cranium, acting through mutations affecting solely an increase in general size. His argument is supported by a graph of face-length plotted against total skull-length for a number of fossil and modern horses, which on superficial examination seems to show that the two sets of points for phylogenetic and ontogenetic growth fall on a common straight line. Robb concludes: "One hundred million years of facial evolution may be summed up in the expression—slope = 0·66", but points out that a logarithmic equation would also express the size relation between face and cranium.



Careful inspection of Robb's graph suggests that the points do not follow a linear trend, and his method of plotting face-length against total skull-length, which includes the former dimension, will tend to obscure any exponential size relation between face and cranium. In fact, when face is plotted against cranium-length (= total skull minus face-length) on a double logarithmic grid, we get the results shown in the figure. Here, we have included all Robb's measurements of fossil horses except those stated by him to have suffered distortion in fossilization, and to his series of modern horses we have added measurements of seventy-six specimens from the British Museum and other sources. The measurements are those defined by Robb in his paper.

Members of the genus Equus have been grouped together, and means only have been plotted for successive size ranges of cranium-length (crosses on the graph). These means, and the number of specimens contributing to each, are shown in the table below. All points for other genera represent single individuals.

Points for Equus lie on a line (*A*) which has a slope of 1·5 up to a cranium-length of about 15 cm., when it becomes bent to the right with a slope of about 1·0; while a backward extension of the line passes extremely close to the single point for a very small fœtal horse. Of the primitive genera with low-crowned teeth, Eohippus and Mesohippus lie exactly on a line (*B*), which has a slope of about 1·8; while the single point for the European genus Hyracotherium lies quite close to this line, and probably does not deviate significantly from it, in view of the magnification of errors at the lower end of the scale with logarithmic plotting. The aberrant bunodont form Hypohippus lies well to the right of both lines. The other genera are advanced types with hypsodont grinding batteries, and all lie about the line of modern horses (*A*), except for one of the two points for Merychippus, which lies close to (*B*).

Clearly ontogeny does not repeat phylogeny in the evolution of the horse's face, and we propose the following modification of Robb's hypothesis. In primitive ancestral horses of the Eocene and Oligocene, the face grew with simple allometry against the cranium, the growth ratio being about 1·8. With the development of hypsodont teeth in the Miocene (Parahippus, Merychippus), a re-organization of skull proportions occurred, doubtless to make room for the enlarged and specialized grinders, and this seems to have been accomplished, not by an increased rate of facial allometry, but by an increase in the size of the facial rudiment at a very early stage of growth, followed by a lower growth ratio throughout the greater part of development. Further measurements may possibly show that the lines (*A*) and (*B*) should be parallel, that is, that the change was not accompanied by a fall in growth ratio. It is interesting to note that the re-organization did not occur when the premolars expanded and took on molar pattern in the late Eocene, but only with the evolution of a fully hypsodont grinding battery.

The position of the point for Hypohippus, Osborn's "forest horse", is remarkable. This genus appears to have sprung from a primitive Oligocene stock, was adapted to a forest life, or at least to soft ground and succulent food, and never developed hypsodont teeth. It has a face only three quarters the length of modern horses with the same cranium-length, possibly as a result of a falling off in relative growth-rate parallel to that already noted in Equus.

It is puzzling to find one point for *Merychippus sejunctus* on each of the lines (*A*) and (*B*), but several explanations are possible, such as an error of measurement, or high variability of skull proportions in this species.

The adolescent growth ratio of the face in Equus is not maintained to adult size, but declines quickly to isometry when the colt is 6–8 months old. While this may be an adaptation to increased size, preventing the face from becoming disadvantageously long, it is possibly a result of normal structural changes in late development, such as the eruption of the last molar or the closure of the sutures.

Our analysis has been limited by the fact that only Robb's measurements of fossil genera were available for study. Other indexes of face-length, such as prosthion to posterior edge of tooth arcade or to cribriform plate, might bring out a different aspect of facial evolution. Moreover, there are serious gaps in our data which could probably be filled in from the material in various museums, notably small fœtal specimens of Equus and stages between Mesohippus and Merychippus. Nevertheless, a remarkably close approximation to the allometric law is shown by both the primitive ancestral series and the few immature modern horses, and we publish this study in the hope that others will be able to fill in the main gaps and so test our conclusions.

MEASUREMENTS OF EQUUS SPECIES (IN CENTIMETRES)

Range	No. in group	Cranium-length	Face-length	Range	No. in group	Cranium-length	Face-length
7–9	1	7·3	7·9	17–18	16	17·5	28·8
10–12	3	11·5	16·1	18–19	15	18·5	30·1
12–13	5	12·4	17·5	19–20	13	19·3	31·2
13–14	5	13·3	19·3	20–21	4	20·3	33·8
14–15	4	14·1	21·8	21–22	10	21·3	35·1
15–16	10	15·5	24·5	22–25	5	22·9	37·3
16–17	12	16·5	26·9	25+	1	26·0	43·0

It is a pleasure to acknowledge our indebtedness to the authorities of the British Museum (Natural History), who kindly allowed us access to their collection of skulls. The original data will be deposited in the library of the Museum.

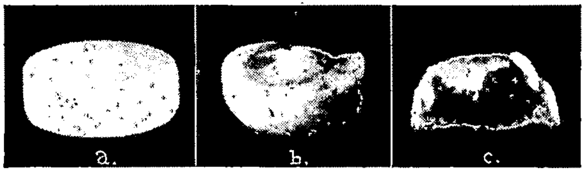
'Ghost' Formation in Subcutaneously Implanted Tablets of Synthetic Œstrogens

THE method of administration of sex hormones by subcutaneous implantation of compressed tablets, first described by Deanesly and Parkes[1], is superior to regular injections in that the tablet, at least for some time, is slowly and continuously absorbed and supplies a relatively constant 'physiological' dosage of hormone.

The kinetics of tablet absorption have been studied[2,3], and the formation of fibrous capsules around tablets implanted into rats[3], rabbits[4], goats[5] and human beings[6,7] described. Geist *et al.*[6] believe that encapsulation may retard absorption and eventually prevent it altogether. Data collected in this laboratory on the absorption from tablets of diethylstilbœstrol and hexœstrol subcutaneously implanted into bovines have indicated that absorption falls off with time at a greater rate than can be accounted for by the decrease in the surface area of the tablet. Encapsulation, which has been observed in most cases, might account for this, but the new phenomenon reported below may be a factor of even greater importance.



(*a*) Tablet of pure hexœstrol, originally weighing approximately 1 gm., after implantation into a cow for 63 days.
(*b*) Ghost obtained by ether extraction of a similar tablet.
(*c*) Ghost cut in half showing hollow structure.

It was observed that tablets of hexœstrol or diethylstilbœstrol, which had been removed from bovines and, after careful cleaning, soaked in several changes of distilled water and dried at room temperature over calcium chloride, were not completely soluble in alcohol or ether, a flocculent residue remaining in suspension. When such a tablet was gently refluxed with alcohol or ether, it appeared to be insoluble, though it was evident that œstrogen was being extracted. The tablet gradually assumed a yellowish translucent appearance and eventually began to float.

Examination showed that the tablet now consisted of a fragile, hollow body of the same shape, and very little smaller than the original tablet (see accompanying illustration), but composed of ether-alcohol insoluble material. This structure, for which I propose the name 'ghost', is evidently formed *in vivo* by infiltration into, and deposition of tissue protein in, the pores of the surface zone of the tablet. Its presence in the tablet is invisible to the naked eye until the œstrogen 'skeleton' has been dissolved away.

In the desiccator the ghosts shrink considerably, forming horny masses which are insoluble in water, acids and alkalis. Tests for nitrogen, sulphur and phosphorus were positive. When a fragment is burnt, it first swells, chars and gives off a smell of burning wool. It probably consists mainly of a scleroprotein formed as a result of the reaction of the animal tissues to the presence of a foreign body.

As yet only tablets of synthetic œstrogens removed from bovines have been shown to contain ghosts. It remains to be seen whether this applies also to

DRY WEIGHTS OF GHOSTS FORMED IN HEXŒSTROL TABLETS SUBCUTANEOUSLY IMPLANTED INTO BOVINES

Wt. of tablet (*s*) after removal from animal (mgm.)	Absorption (mgm.)	Wt. of ether or alcohol extract (*a*) (mgm.)	Wt. of ghost (*b*) (mgm.)	Approx. percentage error in determination of the absorption. Calculated from	
				(*a*)	(*b*)
894*	172	810§	30·5	49	18
889*	172	855	19·5	20	11
742†	362	644	37·5	22	10
849‡	272	811	24·5	14	9

* Five similar tablets weighing 5,240 mgm. were implanted. The absorption from this single tablet is taken as one fifth of the total absorption.

† Twenty similar tablets weighing 1,104 mgm. were implanted.

‡ One tablet weighing 1,121 mgm. was implanted.

§ This extract was re-dissolved in ether, the ethereal solution repeatedly extracted with NaOH, then washed, dried over Na_2SO_4 and the ether distilled off. An oily residue weighing 13·7 mgm. remained. The ghosts may therefore contain some fatty material.

tablets removed from other animals or to tablets of steroid hormones.

Two points in connexion with ghost formation may be of practical importance. First, failure to allow for the weight of the ghost in determining absorption rates by weighing tablets before and after implantation may result in errors amounting to 10–20 per cent (see accompanying table). Second, it seems probable that the infiltration of the 'cortex' of the tablet with so insoluble a substance may considerably retard absorption and perhaps ultimately stop it completely. This would seem to be a likely explanation of the observation of Foss[7] (in the only case in which he used a tablet more than once) that an œstrone tablet removed from a woman and, after cleaning and sterilizing, implanted into another patient, underwent no further absorption.

The effect of ghost formation on absorption, together with the biochemical, serological and histological aspects of the phenomenon, are being further investigated.

Vitamin C and Chromosome Number in Rosa

FIVE years ago Bukin and Zubkova[1] found that wild rose hips contained higher proportions of ascorbic acid when they came from the more northerly or more mountainous regions of the U.S.S.R., proportions rising in the Cinnamomæ group to 15 per cent of the dry weight. It had been known since Täckholm's work[2] that species, or rather forms, in Rosa with the more arctic or alpine distribution were the higher polyploids. Evidently in Rosa[3], as elsewhere[4], there had been a freer post-glacial colonization by the forms with higher chromosome numbers. It seemed therefore that an increase of chromosome number in the rose (as in the apple[5] and perhaps the tomato[6]) might inherently lead to an increase of vitamin production in the fruit, or in the plant generally.

The species named by the Russian chemists as having the highest vitamin contents are in fact recorded by cytologists in other countries as tetraploid, hexaploid and octoploid. Where, however, as in Rosa, polyploidy has occurred within the species, that is, without great morphological change, the systematic name has necessarily lost its genetic and physiological meaning. It is not possible therefore to test the effect of polyploidy until chemical and cytological examinations can be made on the same series of plants.

We are now nearer this goal with the chemical work of Pyke and Melville[7] on species of which representatives in Great Britain have also been examined cytologically. These workers likewise have found that the more northerly forms have the higher vitamin contents, even, they remark, when transplanted to the south. Their facts in relation to the chromosome numbers, so far as I can trace them, are summarized in the accompanying table :

VITAMIN C IN FRUITS OF ROSE SPECIES.

Section	Species	Ascorbic acid	Ploidy	Reference
Synstylæ	*arvensis*	0·08%	$2x$	11
Pimpinellifoliæ	*spinosissima*	0·34%	$4x$	11
Caninæ	*micrantha*	0·40%	$5x$	10
,,	*agrestis*	0·46%	,,	10
,,	*canina*	0·55%	,,	8, 11
,,	*dumetorum*	0·59%	,,	11
,,	*tomentosa*	0·69%	,,	11
,,	*rubiginosa*	0·81%	,,	10, 11
,,	*coriifolia*	1·08%	,,	11
,,	*Sherardi*	1·24%	$6x$*	9
,,	*mollis*	1·26%	$8x$*	9

* Scottish forms ; lower polyploid forms found in England

This provisional arrangement indicates that genetic differences determining vitamin content, irrespective of chromosome number, distinguish species within the Caninæ, but that these differences are of a lower order than those distinguishing the larger groups, Caninæ and Cinnamomæ. At the same time they indicate that polyploidy goes with, and may in itself determine, an increase in vitamin production. This conclusion can be tested by the experimental doubling of the chromosome number in diploid and tetraploid forms, and the results will probably have both particular and general value.

Anemotaxis in Drosophila

Cole[1] has observed that *Drosophila melanogaster* sometimes walks against an air current. Flügge[2] showed that this reaction only occurred when the air was scented, and must therefore be regarded as orientation by smell. However, reactions to air currents without smell do occur in Drosophila.

Comparing several species of the genus, a division can be made between those which show a distinct positive anemotaxis and those which do not. *Drosophila virilis* +, *D. virilis americana*, *D. subobscura* and *D. funebris* turn very sharply towards a tube from which air is flowing and start walking against it, so long as they are not blown away. *D. melanogaster* and *D. buskii*, on the other hand, show no reaction, whereas *D. pseudo-obscura* shows a slight reaction.

Removal of the wings or antennæ or both does not abolish the reaction in the species showing it. Therefore Fraenkel and Gunn's[3] contention that anemotaxis depends on the perception of body deformation caused by the wind seems plausible for Drosophila.

The fact that the two light species observed do not react to wind whereas the four dark species do, may be an indication that the former are not exposed to strong air currents in their natural environment, while the latter are. As wind is a factor which increases evaporation, this is in agreement with some recently published deductions[4], to the effect that a dark cuticle provides better protection against desiccation than a light one.

Nomenclature of Biological Movement

Having read recently with very great interest Fraenkel and Gunn's "Orientation of Animals", I set about making for my own clarification a classification of all the cases I know of what used to be called 'tropistic' movements.

It is clear that three major groupings are possible: a *taxis*, which is a bodily movement of an animal or motile plant in a direction determined by the direction of the stimulus; a *kinesis*, which is a change of rate of movement of an animal (or perhaps motile plant) in response to a change of intensity of a stimulus, but not in a direction determined by the direction of the stimulus—and often producing an aggregating effect superficially similar to that of a taxis; and an *orientation*, which is the placing of the body (usually if not always animal) in a direction determined by the direction of the stimulus. To these three classes many of the cases can be referred.

But the responses of sessile plant organs do not seem to be so conveniently classified. The thigmotropism of Clematis tendrils appears to warrant that name, for the response is a directional one. But the same cannot be said of the so-called 'thigmotropism' of Mimosa leaflets, Mimulus stigma or Berberis stamen, for here the response is not in a direction determined by that of the stimulus. The response in these cases appears to bear a closer resemblance to the photonasty of Oxalis leaflets and the thermonasty of Tulipa flowers. Is one then justified (disregarding—as often becomes necessary for purposes of coherence—mere etymological niceties) in putting these responses under the heading of 'thigmonasty' (or possibly in some cases—as in Stiles's "Plant Physiology"—'seismonasty')? By the same token may the response of Mimosa leaflets to a lighted match in the neighbourhood be called a 'thermonasty', and to ammonia vapour, a 'chemonasty'?

An Inland Record of *Triglochin maritimum* L.

In a previous note[1] I recorded the occurrence of the halophilic alga *Percursaria percursa* Rosenv. from a salt-spring situated at Aldersey[2], Cheshire. Continuing the ecological survey of this spring, I am now able to report the presence of the halophyte *Triglochin maritimum* L. (Naiadaceæ). It occurs in three small colonies growing in the salt-spring and appears to be well established. I should add that during the past year the spring has maintained a salinity of 1,642 parts per 100,000 with only slight variation.

Triglochin maritimum, popularly known as seaside arrow-grass, is a plant frequently found in salt marshes. Its occurrence in a non-littoral region is exceptional and would seem to be unique in so far as the county of Cheshire is concerned. Search of the literature has revealed the fact that Triglochin has occasionally been recorded from the counties of Cambridgeshire, Staffordshire and Surrey.

In Cambridgeshire, the plant appears to have been first reported from Tydd Marsh by Skrimshire[3]. A. E. Evans[4], however, points out that it was never plentiful in that county and has not been found there during recent years. In Staffordshire, J. E. Bagnall[5] mentions records of Triglochin by the independent observers, Shaw, Stokes and Brown. In Surrey, C. E. Britton[6] records its discovery by W. A. Todd from the Thames near Putney.

I am indebted to Mr. A. A. Dallman, of Doncaster, for certain of the references quoted.

Existence of Electromagnetic-Hydrodynamic Waves

If a conducting liquid is placed in a constant magnetic field, every motion of the liquid gives rise to an E.M.F. which produces electric currents. Owing to the magnetic field, these currents give mechanical forces which change the state of motion of the liquid.

Thus a kind of combined electromagnetic-hydrodynamic wave is produced which, so far as I know, has as yet attracted no attention.

The phenomenon may be described by the electrodynamic equations

$$\text{rot } H = \frac{4\pi}{c} i$$

$$\text{rot } E = -\frac{1}{c}\frac{dB}{dt}$$

$$B = \mu H$$

$$i = \sigma(E + \frac{v}{c} \times B);$$

together with the hydrodynamic equation

$$\partial \frac{dv}{dt} = \frac{1}{c}(i \times B) - \text{grad } p,$$

where σ is the electric conductivity, μ the permeability, ∂ the mass density of the liquid, i the electric current, v the velocity of the liquid, and p the pressure.

Consider the simple case when $\sigma = \infty$, $\mu = 1$ and the imposed constant magnetic field H_0 is homogeneous and parallel to the z-axis. In order to study a plane wave we assume that all variables depend upon the time t and z only. If the velocity v is parallel to the x-axis, the current i is parallel to the y-axis and produces a variable magnetic field H' in the x-direction. By elementary calculation we obtain

$$\frac{d^2H'}{dz^2} = \frac{4\pi\partial}{H_0^2}\frac{d^2H'}{dt^2},$$

which means a wave in the direction of the z-axis with the velocity

$$V = \frac{H_0}{\sqrt{4\pi\partial}}.$$

Waves of this sort may be of importance in solar physics. As the sun has a general magnetic field, and as solar matter is a good conductor, the conditions for the existence of electromagnetic-hydrodynamic waves are satisfied. If in a region of the sun we have $H_0 = 15$ gauss and $\partial = 0{\cdot}005$ gm. cm.$^{-3}$, the velocity of the waves amounts to

$$V \sim 60 \text{ cm. sec.}^{-1}.$$

This is about the velocity with which the sunspot zone moves towards the equator during the sunspot cycle. The above values of H_0 and ∂ refer to a distance of about 10^{10} cm. below the solar surface where the original cause of the sunspots may be found. Thus it is possible that the sunspots are associated with a magnetic and mechanical disturbance proceeding as an electromagnetic-hydrodynamic wave.

The matter is further discussed in a paper which will appear in *Arkiv för matematik, astronomi och fysik*.

Energy of Dissociation of Carbon Monoxide

THE energies of dissociation of a number of diatomic molecules have been determined from spectroscopic data, apparently with high accuracy, by the observation of predissociation limits. During the last few years the following values have been proposed for CO: $D(\text{CO}) = 6{\cdot}92$ [1], $8{\cdot}41$ [2], $9{\cdot}14$ [3], $10{\cdot}45$ [4] e.v.; while values of 9·85 and 11·11 also appear possible[3]. Controlled electron experiments suggest 9·6 [5].

The value obtained by extrapolation of the vibrational levels of the ground state is about 11, and support for this value has been given by Kynch and Penney[6]. Herzberg[7] has recently summarized evidence favouring 9·14.

At first sight, the strongest argument for 9·14 is the observation by Faltings, Groth and Harteck[8] that CO is decomposed by the xenon line at 1295 A., but not by that at 1470 A., from which they conclude that $8{\cdot}44 < D(\text{CO}) < 9{\cdot}57$. This conclusion is not based on an examination of the initial act of absorption. The only known absorption in the 1295 A. region is that corresponding to the fourth positive bands. The origins of the (9,0) and (10,0) bands lie at 76,839 cm.$^{-1}$ and 78,010 cm.$^{-1}$. The xenon line 1295 A. = 77,172 cm.$^{-1}$ falls between these bands and, if absorbed from the lowest vibrational level of CO, would correspond approximately to the line $P(35)$ of (10,0). This gives as the upper limit of $D(\text{CO})$ (when the rotational energy is taken into account) a value of 79,722 cm.$^{-1}$ = 9·88 e.v. (not 9·57 e.v. as stated by Herzberg[7]). Actually, it is doubtful whether such a high rotational line as $P(35)$ would be observed at room temperature, and absorption, if it is due to CO, would probably occur from a higher vibrational level, corresponding perhaps to the (13,2) band, in which case the dissociation limit may be placed as high as 10·1.

Taking the first act of absorption as

$$\text{CO}(X^1\Sigma) + h\nu = \text{CO}(A^1\Pi),$$

and assuming a life not less than 10^{-8} sec. for $A^1\Pi$, then at atmospheric pressure each molecule experiences at least 100 collisions before radiating. It seems to us that this gives a reasonable chance for a reaction such as

$$\text{CO}(A^1\Pi) + \text{CO}(X^1\Sigma) = \text{CO}_2 + \text{C}$$

to proceed with quantum efficiency approaching unity. The state of the carbon atom might be either ^1D or ^3P; the former if spin is to be conserved, the latter if not. In either case the reaction is strongly exothermic. The failure of the xenon line 1470 to induce photodissociation may be due to the reaction requiring an activation energy.

Estimates of $D(\text{CO})$ less than 10 take no account of the non-crossing rule of Hund, and Neumann and Wigner[9]. This rule states that potential energy curves of molecular states of identical species cannot cross. Whether the rule is rigorous when the nuclear and electronic motions are not separated needs further examination, but at least we see no reason for anticipating a failure of the rule in the lowest energy curve of CO. If this curve has only one turning point then the non-crossing rule requires unequivocally that $D(\text{CO}) > 10{\cdot}3$, and would agree well with the predissociation limit at 11·11 e.v.

The dissociation energy of CO+ is 2·6 e.v. less than that of CO ($D(\text{CO}^+) = D(\text{CO}) + I(\text{C}) - I(\text{CO})$). Three electronic states of CO+ are known, namely, $X^2\Sigma^+$, $A^2\Pi$ and $B^2\Sigma^+$, extrapolating to dissociation limits of about 9·8 (a very long extrapolation), 9·2 and 9·4 e.v. respectively. Since the two $^2\Sigma^+$ states must give different products of dissociation, it would appear, on the evidence of the $B^2\Sigma^+$ state, that $D(\text{CO}^+)$ is 7·4, and $D(\text{CO})$ is about 10, and on the evidence of the $A^2\Pi$ state that $D(\text{CO}^+)$ is 9·2 and $D(\text{CO})$ is 11·8. All that may fairly be deduced from present evidence on CO+ is that $D(\text{CO})$ is unlikely to be much less than 10.

We have also re-examined nitrogen. The accepted value $D(\text{N}_2) = 7{\cdot}38$ is based on the identification of the upper state of the Vegard–Kaplan bands with the

$A^3\Sigma$ level. This is at variance with numerous measurements of the excitation potential of the second positive bands[10]. Applications of the non-crossing rule to N_2 and N_2+ agree in giving $D(N_2)$ at about 9 e.v., but it is only possible to avoid crossing of the N_2 potential curve for $B^3\Pi$ and another $^3\Pi$ state dissociating to $^4S + {}^2D$ by assuming a small maximum in the $B^3\Pi$ energy curve. We incline to the opinion that many of the upper potential curves of CO and similar molecules must have more than one turning point: without such an assumption it is difficult to make the various lines of experimental evidence fit together. Details will be given later.

Summarizing, our suggestions are that $D(CO)$ lies between 9·85 and 11·11 e.v., and $D(N_2)$ is about 9 e.v.

A Modified Patterson Function

Recently Yü has suggested in Nature[1] the synthesis of a new modification of the Patterson function, which has proved very useful in structure analysis of crystals. For the one-dimensional case, Yü's method is to calculate the modified function P_n given by the following series

$$P_n = \sum_h a_{nh} E_h \qquad (1)$$

at the points $X_n = \frac{n}{N}$, where N (taken to be an even number for the convenience of our discussion) is the number of equal sub-divisions into which the unit translation is to be divided, and the E's are the 'idealized' structure factors with atomic numbers replacing the appropriate atomic factors. When the constants a_{nh} are so determined that

$$E_h = \sum_{n=-N/a}^{+N/a} P_n \cos 2\pi h X_n \qquad (2)$$

for every vector h of the reciprocal lattice, the function P_n gives an approximate representation of the product $Z_i Z_j$ or a sum of such products corresponding to one or more interatomic vectors $r_{ij} = X_n$, provided that N is chosen sufficiently large and the series (1) is not cut off at too small values of h. These constants a_{nh} can be determined from the following relation:

$$\sum_{n=-N/2}^{+N/2} a_{nh} \cos 2\pi h' X_n = (-1)^h \cdot \frac{h'.\sin h'\pi}{\pi(h'^2 - h^2)}. \qquad (3)$$

Evidently, Yü's method admits of easy generalization to two- or three-dimensional cases, which require another set of constants b_{nh}, to be determined by the following relation:

$$\sum_{n=-N/2}^{+N/2} b_{nh} \sin 2\pi h' X_n = (-1)^h \cdot \frac{h.\sin h'\pi}{\pi(h'^2 - h^2)}. \qquad (4)$$

An obvious disadvantage of this method is the computation of these sets of constants for a moderately large value of N, which is undoubtedly very laborious.

I wish to point out here the simple limiting forms of the constants a_{nh} and b_{nh} when N is allowed to tend to infinity. Equation (3) takes the following form

$$\int_{-\frac{1}{2}}^{+\frac{1}{2}} a_h(X) \,.\, \cos 2\pi h' X.dX = (-1)^h \frac{h'.\sin h'\pi}{\pi(h'^2 - h^2)},$$

when N becomes infinite. It follows immediately that $a_h(X) = \cos 2\pi h X$. Similarly, $b_h(X) = \sin 2\pi h X$. It is thus obvious that (1) is an approximate form of Fourier representation of the 'idealized' Patterson function. It differs from the Patterson function in the fact that the E's (which can only be approximately determined from the experimental intensities) are used instead of the $|F|^2$'s; this difference accounts for the possible 'sharpening' of the Patterson peaks in Yü's modified function. Hence it may be inferred that (1) will not be more rapidly convergent than the Patterson function if the same degrees of approximation are to be attained; and that it will not entirely eliminate the diffraction effects inherent in the latter function or other related Fourier representations because of experimental limitations and uncertainties. Although I agree with Yü in realizing the desirability for a new interpretation of the Patterson function or related functions, it is my opinion that Yü's method does not offer a better solution to the structure analysis of crystals than the original function of Patterson.

Radiation from Flames

As is well known, R. von Helmholtz found that the radiation from carbon monoxide flames was nearly 2·5 times as great as that from hydrogen flames. This appears to be generally interpreted as indicating that carbon dioxide radiates more powerfully than water vapour[1]. But the opposite is the case; water vapour radiates twice as powerfully as carbon dioxide under similar conditions of temperature, etc[2,3]. Helmholtz's results (which at first sight are all the more surprising because hydrogen-air flames are some 100° C. higher in temperature than carbon monoxide-air flames) would appear to be due to the more rapid cooling of the hot products surrounding the outer cone in the case of hydrogen flames than in the case of carbon monoxide flames, for Hartley[4] has shown that the overwhelming proportion of the radiation from flames comes not from the interconal gases but from these hot products. It would appear that the more rapid the combustion the greater the turbulence in these products, and hence, owing to the more effective intermingling with the surrounding air, the more rapid the cooling.

Helmholtz also found that when the gases fed to the burner were pre-heated the amount of radiation from the flame was decreased—in spite of the fact that the flame gas temperature must be higher. He and others believed that this supported the view that the (infra-red) radiation from flame gases is of chemical origin, but there is now definite experimental evidence that it is due to thermal causes[2]. I think that the explanation of Helmholtz's pre-heating experiments is probably similar to that given above, namely, a more rapid cooling of the hot products outside the outer cone due to greater turbulence.

Publication of Scientific Research carried out by Industry

ON p. 322 of NATURE of September 12, Dr. Denbigh charges "many British firms" with refusing to allow their staffs to publish their scientific work. He proceeds to write of "industrial companies" without qualification, and to draw a general comparison between British and American industry. It seems, therefore, that by "many" he means "practically all". Accordingly, it should be pointed out that there is at least one important firm to which his statements do not apply, and, therefore, that evidence is needed to show that the practice he denounces is typical of British industry.

When I became an employee of the General Electric Co., Ltd., twenty-three years ago, I was impregnated with the academic tradition about publication. During those years I have had the fullest opportunity to observe the policy of my employers in this matter, and I can testify that I have never found anything contrary to the highest form of that tradition. Even those of them who are most fully imbued with commercial ideas, and might be expected to take the narrowest view of the company's interest, have realized that the indirect benefits of publication (one of them is a good reputation in academic circles) outweigh any direct benefits of secrecy. Publication in the academic sense has always been regarded as a normal activity of the research staff, and has been subject only to such censorship as a professor might impose on his students to prevent the publication of immature work. Apart from formal publication, the staff have always been encouraged to place their special experience at the disposal of individual academic workers to whom it might be of value. The only restriction, arising out of commercial considerations, has been a delay of perhaps a fortnight on a few occasions in dispatching a paper (or a letter to NATURE), in order to allow a patent specification to be filed.

I do not say that no detail of any industrial process has ever been kept secret; but the few secrets that have been kept (apart of course from those affecting national security) are, in my opinion, of no interest to anyone but a commercial manufacturer.

Those who are still under the delusion that secrets are the life-blood of industry may find it difficult to believe that any firm could long pursue so enlightened a policy. It may be well, therefore, to point out two things. First, the industrial use of many scientific discoveries can be adequately protected by patents, which involve publication. Second, most industrial problems have several alternative solutions. What a manufacturer usually would like to learn from his competitors is not simply how to do something, but the way of doing it that has been found the best. The method most scientifically interesting is by no means always the most commercially effective. By publishing scientific work that indicates some new alternative, a manufacturer does not disclose the method he is actually using.

Scientific Literature for Enemy Prisoners of War

A SMALL organization has recently been formed[1] for the purpose of sending copies of scientific papers to scientists who are enemy prisoners of war in British hands. The idea is to keep alive the spirit of discovery, so that imprisoned enemy scientists may be helped to remain mentally active and thus become useful world-citizens again after the War.

All the authorities who have been approached have been sympathetic and helpful. This applies to the Director of War Prisoners, the Special Division of the Swiss Embassy concerned with the welfare of German, Italian and Japanese prisoners, Le Comité international de la Croix-rouge (London Delegation), and the War Prisoners Aid Section of the Young Men's Christian Association. The helpfulness of Mr. John Barwick, of the latter organization, must be particularly mentioned.

Scientists receive many reprints of scientific papers which they do not want to keep permanently. I should be most grateful for reprints, which would be directed through the proper channels to the appropriate scientists in prisoner-of-war camps. Fairly old papers would be useful as well as new ones. Enemy prisoners are unlikely to have seen British or American papers published later than August 1939, and many earlier ones would also be useful. Copies of NATURE would be particularly acceptable, and some of those who receive this journal regularly may perhaps consider contributing their copies after reading them at leisure. Authors are asked to send reprints of their own papers.

Those who are willing to contribute reprints or copies of NATURE or other journals should send them to me at Burnt Oak, Kidlington, near Oxford. They are asked to give their names, so that they may receive acknowledgements and periodical reports on the progress of the scheme.

No time will be spent on the organization of this scheme which would otherwise be spent on the war effort.

Scientists who are not already sending educational books to British prisoners in enemy hands may care to know that this can be done through the office of the Educational Books Section of the Prisoners of War Department of the British Red Cross Society and Order of St. John of Jerusalem, at the New Bodleian Library, Oxford. This office is kindly keeping in touch with our movement, so that matters of mutual interest may be discussed.

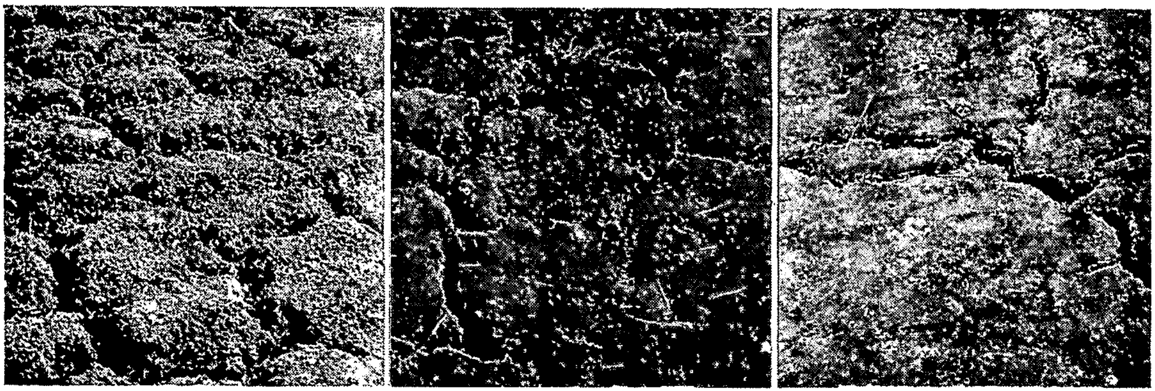
FUNCTION OF SOIL CRACKS

By Dr. A. SREENIVASAN

Institute of Plant Industry, Indore

A CHARACTERISTIC feature of heavy soils such as the black cotton soil is their extensive cracking during summer fallow. Wide fissures are formed as a result of the shrinkage of the soil colloids under the baking action of the hot sun during summer months. These cracks vary from a fraction of an inch to 3–4 in. in width, and are often several feet in depth. It is generally recognized that cracking results in an improvement in the physical properties of the soil, but the factors which determine the character of cracking in field soils have remained rather obscure. Interesting information has been obtained in the course of a survey of the nature and extent of surface cracking in different fields under cotton in the Institute area. The technique adopted was as follows :

The fields were left undisturbed after the last cotton picking towards the end of January. At the hottest part of the year in mid-May, five plots measuring 10 ft. by 10 ft. were marked out at random in each field. Each of these plots was further subdivided into 100 squares, 1 sq. ft. each, and a survey of all the cracks intercepting the lines of these smaller squares mapped on graph-paper. Crack width was measured with a straight edge and, where necessary, by using a pair of dividers. The width was measured along a direction perpendicular to the line of interception with the crack.



Well-drained good field | Well-drained medium field | Badly drained and eroded field

Crack formation in field soils.

The number of cracks of different widths obtained as above in typical fields of known rich, medium and poor fertility are given below (Table 1).

Table 1. Frequency of cracking in different fields.

Width of crack* (in.)	Number of cracks (average per plot)			Remarks	
	Field 7 : Good, well-drained	Field 41*s* : Medium well-drained	Field 27 : Poor, badly drained and eroded	Significance	Critical difference (No. of cracks)
0·5 and less	78·8	16·2	0·4	$P<0{\cdot}01$	18·4
0·5–1·0	60·0	37·4	4·6	$P<0{\cdot}01$	13·5
1·0–1·5	20·2	28·4	31·0	Insig.	—
1·5–2·0	47·6	35·0	23·4	$P<0{\cdot}01$	6·5
2·0–2·5	39·6	37·6	34·0	Insig.	—
2·5–3·0	4·6	4·4	7·2	Insig.	—

* There were few, if any, cracks of width greater than 3·0 in.

Cracking was, on the whole, extensive in the good field, but only meagre in the poor field, the medium field being intermediate in character (see accompanying photographs). The chief difference between the three fields lay in the significantly larger number of small cracks (less than 1·0 in.) in the well-drained fields as compared to the poor field.

An idea of the surface area of cracking was obtained by multiplying the number of individual cracks falling into different width groups (Table 1) by the average width in each instance and summing up these values for each of the three fields :

Table 2. Index of surface area of cracking (average).

Field 7 (good)	Field 41*S* (medium)	Field 27 (poor)	Significance	Critical difference
275·0	225·6	179·6	$P<0{\cdot}01$	34·8

More or less similar results were obtained in surveys carried out over a larger number of fields. It must be emphasized here that these results relate only to fields of the same soil type but differing in their fertility.

No attempt was made to determine the depth of cracking, as it was observed that the fissures leading downward were seldom either vertical or uniform in width. In general, however, the depth to which the cracks extended was often least in fields of low fertility ; in other words, the cracking tended to be superficial in these fields. Furthermore, the soil along the cracks in all the fields possessed a friable structure. But, while the soil in the clods from the good and, to a less extent, medium fields also possessed a loose, friable structure, breaking into smaller crumbs with gentle pressure between the fingers, that from the clods of the waterlogged field was usually hard and broke under pressure with a definite cleavage and a somewhat shining surface.

The loose soil in and around the cracks is subjected to alternate heating and cooling during days and nights over considerable periods of time. Such alternate heating and cooling bring about a state of aggregation[1] which, on account of the differences in the degree of cracking, is obviously more uniform throughout the well-drained fields than in the poor field.

Surface (0–6 in.) and sub-soil (6 in.–12 in.) samples for further laboratory examination were taken by a suitably improvised technique from along the cracks and from inside the clods of the fields of medium and poor fertility. These could not be taken from the rich field as the cracks were too numerous and as, moreover, the soil inside the clods tended to become pulverized readily even under light touch. The results of analyses which will be detailed elsewhere indicated in general that the differences in physical properties between corresponding crack and clod samples were less marked in the well-drained field than in the eroded field. With the latter, there was greater uniformity between surface and sub-soil samples taken along the cracks than from the clods. Thus, the main contrast between the well-drained and poorly drained fields was in the depth to which good tilth existed below the surface.

These observations could be explained as principally due to the fact that, by means of these cracks, considerable quantities of soil material are periodically carried down from the surface to lower depths within the soil, both on account of the hot summer winds and by the early June rains[2]. It is also probable that the first showers of the monsoon are followed by the swelling up of the colloidal masses from below[3]. There is thus a pronounced circulation of the soil material, a result similar to that brought about by cultivation. This 'self-ploughing and sub-soiling'[4] is so intense that mechanical cultivation often becomes ineffective. Experiments carried out for more than five years at this Institute[5] have shown conclusively that summer cultivation with or without inversion to different depths before *Kharif* sowing is not necessary for the rain-sown, unmanured cotton crop. It has been shown similarly that preparatory cultivation on the black soils of Koilpatti (S. India)[6] and in the Sudan[7] is superfluous and may, at times, be decidedly harmful[8]. Even in temperate and cooler regions the effect of the traditional thorough cultivation has begun to be doubted. Thus, at Rothamsted[9], it has been shown that cultivation in excess of that needed to keep down the worst weeds does not confer any further benefit and may even result in a reduction in yield. It would, of course, be useful to adopt summer ploughing in a weed-infested field such as, for example, in the eradication of *kans* (*Saccharam spontaneum*) and *dhub* (*Cyanadon dactylon*), for it is found that hot-weather ploughing exposes and kills the roots[10].

An interesting observation was that the concentration of soluble salts in the soil along the cracks was always higher than in the corresponding sample from the clods (*cf.* Mosseri)[11]. This would suggest the possibility of reclaiming saline lands by promoting crack formation, which will be followed by the washing down with the first rains of the deleterious salts along the crack edges.

Another significant observation related to the rather wide difference in the swelling capacity of the surface and sub-soil samples taken along the cracks, this difference being somewhat less pronounced in the poor field. In either field, the samples from clods did not show any appreciable difference in this property. It would appear that the greater difference with depth in this respect may account for the higher degree of cracking in the well-drained field.

It may be concluded from the foregoing that the development of soil cracks during summer fallow must be promoted. This can be done (i) as already stated, by avoiding, or at any rate reducing to a minimum, cultivation during summer fallow, and (ii) by allowing crop plants to remain in the fields for a certain period (say, until about the beginning of May) after harvesting operations are over. In the latter case, the standing plants will tend to put out ratoon growths. This will be accompanied by deeper penetration of roots followed by new lines of cracking. I have observed that the juxtaposition of crop rows with field cracks have confirmed that standing crops greatly facilitate soil cracking. A possible objection to this practice is that the ratoon crop may deplete the soil of its fertility; while this may be true in some measure, it should be pointed out that if the standing crop is removed by about the middle of the hot season, the recuperative power of the soil during the hot period, coupled with the advantages of better cracking, may offset this depletion. If, however, such crops have had, during their normal period of growth, any disease or insect attack, it may be necessary to pull them out as soon as harvest is over.

It is of interest to compare here the beneficial effects on crop growth resulting from (1) building up of the loose surface soil artificially to different thicknesses[12], and (2) application of 'fired' soil in the sub-surface regions[7, 13]. In heavy soils, the wide cracks formed as a result of extreme variations in swelling and shrinkage is indeed Nature's efficient method of heating and weathering the sub-soil layers. This uniformity with depth in the surface soil will obviously promote greater bacterial activity with consequent production of mucus, which aids in the formation of water-stable aggregates [14, 15].

The advantages of cracking during any one season will admittedly be small, but the cumulative effect over prolonged periods will no doubt be appreciable enough to increase the fertility of a field. Besides, in a waterlogged field, the development of these cracks, followed by the ingress of the surface soil through them, will improve the permeability and drainage conditions in the field.

REBUILDING GREAT BRITAIN

THE Reconstruction Committee of the Royal Institute of British Architects, which has already published five interim reports dealing with planning and amenities, war-time housing, building legislation, reconstruction of the architectural profession and legislation affecting town and country planning in Great Britain, has now issued a first general statement of conclusions, which in some respects provides an interesting parallel to the recent report of the Scott committee.

Dealing first with human needs as a foundation for reconstruction, the statement points out that from the point of view of physical reconstruction, the essential needs of the individual are suitable work in clean, healthy and cheerful surroundings and a convenient and attractive home, forming part of a community capable of evoking local patriotism and civic pride. The most essential public needs for physical reconstruction are a firmly established agriculture, a prosperous, well-located industry, and an efficient system of transport. As regards the practical and æsthetic needs, the public is right in expecting and demanding that the opportunity afforded by post-war reconstruction shall not be thrown away; buildings and towns must be both convenient for use and pleasant to live in. A civic sense has been slowly but firmly growing up in the people, one form of which is seen in the demand that the slum areas should be no longer tolerated and in regarding the effect of war damage in these areas as an opportunity for total reconstruction. In another form it is seen in the determination to check ribbon development, because that constitutes an offence to the eye, and also in the positive demand that cities and towns should be better to look at and better planned.

In outlining a national plan to meet these needs, the statement points out that assurance is required that the Government's positive policy will deal with individual as well as public needs, and this must be demonstrated by the creation of machinery to produce a national plan as well as to execute it, by the creation of the plan and by its execution. Of these four positive acts the last cannot be contemplated until after the War, but the difficulties in undertaking the other three in war-time must be overcome, at least to the extent of producing the general lines of each before the end of hostilities.

With regard to the machinery of planning, the statement points out that a national authority is essential to obtain a national plan, and at least four Government departments will be deeply involved. Unless all the departments concerned are amalgamated into one huge department, the national planning authority must be so devised that it has the power to co-ordinate the proposals of the various departments and to over-rule the views of any single department when necessary for the sake of the plan as a whole. Some parts at least of the plan will be such that neither private enterprise nor local authority will be able to execute them, and a central executive body will be required to ensure the execution of such work. Accordingly, in addition to a national planning authority and a national planning commission, a development commission will also be required. This commission should be made responsible for ensuring the smooth working of the plan in all developments, whether executed by itself, by Government departments, by local authorities or by private enterprise. It would also be responsible for providing local authorities and public utility companies with the necessary credit for the execution of local schemes. In this connexion attention is directed to the Tennessee Valley Authority as a precedent for public development.

In regard to planning authorities, the organization of the whole would presumably consist of a central planning national authority with its regional officers, and groups of local authorities to prepare the local or sub-regional schemes.

A national code of legislation should be compiled to cover the whole of Great Britain, administered from a single office in each locality. This national code should be in three parts, the first dealing with planning for human needs, or what might be termed a code of living standards. The second would deal with structural standards and the third with the financial provisions which will be necessary to achieve these ends.

It is suggested that the code of living standards might be in two parts dealing respectively with standards of amenity which might be advisory, not compulsory, and with health and safety precautions, which should be mandatory. Under this national code, only one application should be necessary for the approval of plans, but submission of plans for approval should be compulsory for all types of buildings. In addition, the appointment of a national building board is visualized, as outlined in a previous interim report.

In regard to the organization of the building industry, co-ordination of the main groups of the industry, the employers, the operatives, professional bodies and the manufacturers and distributors of building materials can best be achieved through the machinery of a central council which might form a liaison with Government departments. So far as technique is concerned, it is essential that those adopted should provide good building with the utmost possible economy as well as the maximum output, and a proper balance between first cost and cost of maintenance.

Surveys already carried out by the Committee indicate that public control of the building industry must continue after the War, and the techniques adopted in building will affect and be affected by the public policy on imports, transport, etc. Coupled with centralized control, the Committee therefore strongly recommends centralized research, expanded and made independent of outside donations by a sufficient Treasury grant. This centralized research should be under the charge of the Building Research Organization.

In regard to finance, the Committee urges that in drawing up its plans for reconstruction, the Government should relieve local authorities of regions of the financial burden, simplify the machinery for dealing with private interests which may be affected, and arrange for the dispatch and distribution of the resources of the building industry in whatever manner seems best for the national interest. With regard to filling in the plan, it is suggested that all land without exception should be publicly controlled, whether publicly or privately owned.

The great building programmes will be so profoundly affected by any changes in the location of industry that local authorities will only be able to make tentative estimates of their needs until Government policy on this subject is formulated. In the existing large towns or 'conurbations', the need for the centralization is generally agreed, and building of a certain number of new satellite towns is complementary to this decentralization. Regrouping within the boundaries of existing towns is as important as decentralization, and new towns should, when possible, be developed from existing small towns or villages.

A local improvement fund for each district is recommended and a very close relation should exist between the housing and town planning committees in an area. Housing should form part of a well-conceived plan for re-equipping the country, and in that it should incorporate standards fulfilling the desires and requirements of the population, should be able to call for the best technical advice and knowledge available. The selection of suitable architects requires careful attention. The post-war housing needs cannot be estimated, but the position facing the building industry must be handled on a national, not a local, scale, and only by careful planning ahead can the post-war housing needs be met. The emergency and the long-term programmes must fit into a national scheme which takes account of the future redistribution of industry and of methods of construction. There is no suggestion that the provision of housing by private builders should be discouraged, provided excessive profits on land and buildings are eliminated and that standards both in design and construction are reasonably good. A national policy for house production should be formulated to co-ordinate the work of the various house-building agencies and constitute more even distribution of work and results. Research into consumer needs should also be encouraged.

The final section of the statement deals with the importance of the architect's contribution, both in modern planning and in the public control of the appearance of buildings, and it is stressed that it is essential that every planning authority should employ a well-qualified architect as a principal officer directly responsible to that authority.

LEAD-CALCIUM TEST CASTINGS

CLOSE control of the calcium content is required in the manufacture of lead-calcium cable sheath. This is not easily attainable because the calcium content is small and a variable amount is lost while the alloy is molten, despite the special techniques used to minimize air contact. Conventional methods of determining this loss are slow and costly. A new procedure described by G. M. Bouton (*Bell Lab. Rec.*, 20, No. 10; June, 1942) arises from Bell Laboratory studies of lead-calcium alloys which have shown that the surfaces of ingots, chill cast with little agitation, become progressively duller with increasing calcium content. Fissuring then sets in and leaves bright areas exposed, depending in extent on the amount of calcium present. Under controlled conditions these markings provide a quick, accurate measurement of the calcium content.

The sample is melted in a small iron crucible, the lip of which is brought close to the mould before pouring, to minimize exposure to the atmosphere. The mould itself is an iron plate with a tapered depression about 4 in. long and $\frac{5}{8}$ in. wide, milled on its surface. To ensure reproducible results, casting is done in a 'Cellophane' chamber through which passes air of known carbon dioxide and moisture content. Since both affect the results, they are first removed by passing the air over potassium hydroxide and calcium chloride. A definite percentage of each is then replaced in the casting chamber, and the melt poured. Representative figures are 50 per cent. humidity and 0·02 per cent carbon dioxide. Decreasing moisture and increasing carbon dioxide make the surface brighter, and vice versa. Alloys of calcium content outside the range of the method may be tested by diluting or enriching them with lead-calcium alloys containing appropriate amounts of calcium. This method of determining the calcium content in cable sheath is reliable and more rapid than chemical analysis or metallographic techniques.

FORTHCOMING EVENTS

(Meeting marked with an asterisk is open to the public)

Saturday, October 3

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. David Williams: "Mineral Resources of the U.S.S.R".

Tuesday, October 6

CHADWICK PUBLIC LECTURE (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 2.30 p.m.—Sir Leonard Hill, F.R.S.: "The Interrelation of Clothing and Shortage of Fuel in matters of Health".*

Friday, October 9

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. E. Watson Smyth: "The Training Activities of the Ministry of Labour".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEAD OF ENGINEERING DEPARTMENT (MECHANICAL AND ELECTRICAL) in the School of Mines and Technology, Treforest—The Director of Education, Glamorgan County Hall, Cardiff (October 12).

LECTURER IN ELECTRICAL ENGINEERING—The Secretary, University College, Dundee.

REPORTS and other PUBLICATIONS

NUTRITIONAL RESEARCH

THE field of nutrition tends daily to enlarge. It has already established itself over considerable areas long considered to be exclusively the domain of medicine and concerned with the problem of curing and preventing disease. It has invaded chemical engineering; for example, it now requires plant for large-scale dehydration of foods with minimum destruction of essential nutrients. In its urgent need for precise analytical data about the composition of foods and diets, it has needed to mobilize not only the analytical chemist, but also the bio-assayist—with the statistician in close attendance—the physical chemist and physicist, with a special call on those having experience in X-ray crystallography, in spectroscopy, both visual and ultra-violet, and most recently in polarography; this is one of the latest techniques to be added to the many, such as chromatography, that have stimulated and been stimulated by our increasing knowledge about the nutrients present in what we and our domestic animals eat.

When it comes to applying in practice what has been learnt in laboratory, in field and in hospital ward, and applying it to the largest possible number of people over the largest possible areas of the world, others with expert knowledge are needed to add their counsel to that of the scientific investigator and the practising physician. The anthropologist, the educationist, the sociologist, the geneticist, the economist, among many, are able to contribute data of value to those who wish to direct the maximum quantity of the best foods to the places where the people most need it, and to secure that the people who most need it are persuaded to eat it, and can afford to do so—to eat it, moreover, before any appreciable proportion of its essential nutrients has been lost.

That the problems embraced under the general terms 'nutritional research' and 'food policy' are many, complex and interlocked is a fact of which increasing numbers of people—and not least the workers in nutrition themselves—are becoming aware. This awareness is doubtless largely responsible for the foundation of the Nutrition Society in August 1941, and the great success of its meetings held since then in England and Scotland and reported from time to time in NATURE. At these meetings there has been free interchange of information and opinion between a great variety of specialists, all, however, legitimately sheltering under cover of the nutritional umbrella. In particular, the contact between clinicians and veterinarians at these meetings has been a matter of favourable comment.

The same awareness is presumably responsible for the interest shown by the writers of letters to *The Times* on the proposal for a Nutrition Council put forward in its columns on August 28, and since then supported by the *British Medical Journal* in its issue of September 26. On the whole, the proposal has been received with favour, but certain distinguished physicians have argued that the Medical Research Council is in effect, or should be, a Nutrition Council and that to set up yet another co-ordinating body would be unjustifiable, especially in war-time, because unnecessary.' It has also been suggested that the Nutrition Society itself could exercise the required functions. These comments, and the original proposal for setting up a new *ad hoc* Nutrition Council, its structure and powers, obviously call for close examination.

First of all, the part to be played by the Nutrition Society can easily be defined. It is a scientific society—a 'learned' society, indeed, although it confers no diplomas or post-nominal initials—and seeks to promote, among those who experiment and observe, the dissemination of knowledge about nutrition gained through experiment and observation. It is not concerned with educating the public or its representatives, at one end of the scientific scale, or with planning research, at the other. It is no more, and no less, suited to become a Nutrition Council than, say, a joint committee of the Chemical and the Physical Societies would be suited to become the Department of Scientific and Industrial Research. This is, of course, not to deny for one moment that the personnel of a Nutrition Council must include members, even perhaps representatives, of the Nutrition Society.

It has been ingeniously argued by Lord Dawson of Penn that the Medical Research Council's recent appointment of Prof. C. R. Harington as director of the National Institute of Medical Research, in succession to Sir Henry Dale, should so clearly show its awareness of the essential part played by non-medical sciences in medical research as to overcome all scruples about leaving nutrition research in the hands of the Council. Lord Dawson has also directed attention to the many branches of science that have been mobilized to attack the diverse problems with which the Medical Research Council has been for some years concerned, and to the fact that a high proportion of its own staff is not medically qualified. This, he contends, proves not only that the Council is aware of the need for collaboration between medical and non-medical men of science, but also that its ability in the past to co-ordinate their activities, and the brilliant conclusions to which they have jointly been able to bring so many and so varied investigations, proves its fitness to be what, in fact, it is—a Nutrition Council.

We suggest that this misses the point of those who argue in favour of a controlling body representative of sciences other than the purely medical, along, of course, with full and probably preponderating representation of all the relevant specialized branches of medicine itself. This is a view to which Lord Horder and Sir Charles Wilson would seem to subscribe. It is based upon the simple principle that those who are to play an essential part in elucidating scientific problems should be entitled to share in decisions as to what problems are to be tackled and how. If the biochemist, the analyst, the food technologist, and many others to whom we have referred already, are essential to the increasing elucidation of nutritional facts and principles, then surely a Nutrition Council must include representatives of chemistry, agriculture and engineering, as also obviously of physiology, pharmacology, biology, statistics and so on, irrespective of whether they are medically qualified or not. Medical men must, in any event, be there also in full force, by virtue of their dominating and central interest in the bearing of nutrition upon health, but a Nutrition Council constituted *ad hoc* would attack—if it functioned aright—its problems from the point of view of human and animal nutrition and feeding, and not from the point of view of medicine only.

It is perhaps of interest to note that the opinion held by Lord Dawson—and also by Sir Francis Fremantle—that it would be satisfactory to leave the direction of nutritional research as a whole in the hands of a purely medical body, has not been put forward in public by any medical men who have been directly engaged on, or especially interested in, nutritional problems. Such medically qualified workers seem in general strongly to favour joint action and equal status with their non-medical scientific colleagues. It is, further, we feel convinced, not a view to which the Department of Scientific and Industrial Research, which controls the work of the Food Investigation Board, could possibly subscribe, nor yet the Agricultural Research Council. Further, if nutritional research is to be controlled by a body that is primarily medical, has not the Ministry of Health as much claim to be that body as has the Medical Research Council ? Finally, since the object of nutritional research is to find out what are desirable foods and to investigate means of producing them, the Ministry of Food, with its now highly effective and far-seeing scientific staff, must come into the picture.

The more the problem is examined, the stronger appears the case for a new body, linking up with all those organizations and departments that have any concern with nutrition and food problems—but in no way interfering with their legitimate autonomy—acting primarily as a centre of information about the results of past research and the nature of research in progress and to an ever-increasing degree guiding, without actually dictating, the direction of new investigations. Such a body, if constituted as a Nutrition Council, might, like the three existing research councils, be a committee of the Privy Council; alternatively, as has been suggested by the Association of Scientific Workers, it might be one of the main committees of a Central Scientific and Technical Board. This question, however, though obviously of importance, is at the moment of secondary interest. We are much more concerned with ensuring on the nutritional front a far greater degree of genuine active collaboration than there is reason to believe now exists between the Medical Research Council, the Ministries of Agriculture, of Health, of Food, and of Labour and National Service, the Board of Education, the Department of Scientific and Industrial Research, the three Service Departments and the considerable array of industrial laboratories (including Research Associations) that are engaged in one way or another in investigating problems with a direct or indirect bearing on nutrition.

It cannot seriously be maintained that co-ordination, even co-ordination of existing knowledge about methods and results, is at present adequate between the large number of laboratories, hospitals and experimental farms in Great Britain involved in nutritional studies in the widest sense. There are many actual and potential workers in this field who would enthusiastically welcome some recognized centre to which they could turn for advice about what to do next and how to do it, in the best interests of the nation at war. At meetings of scientific societies it happens over and over again that workers discover others to be investigating problems allied to, or even the same as, those on which they have themselves been working, independently and, as they thought, solely. How much better had contact been made before the work was well in hand.

We have suggested above that co-ordination, if it is to be effective, must include several major State Departments, besides the organizations specifically devoted to research, both outside and inside industry. This appears to be generally recognized, but it has led to a confusion of thought that, if not removed, might have unpleasant or even disastrous consequences. It is a fundamental principle in a country organized as a parliamentary democracy that all questions of major policy, affecting the everyday life and health of the people, must be decided by that people, speaking and acting through its constitutionally elected representatives, the Government and the Cabinet. Nor can there be the slightest doubt that decisions about the people's food, what it shall be, how it shall be distributed and what it shall cost in terms of real wages, are decisions on a matter of major policy. It follows inevitably that food policy must be determined by Parliament. To suggest that an *ad hoc* organization of experts shall make decisions on such matters of policy is not merely to propose a restriction on the legitimate rights of the ordinary citizen, but also to condone the introduction of the thin end of the wedge of the totalitarian State. It must be vigorously opposed by all men of democratic goodwill, no less by those who support the formation of a new Nutrition Council than by those who oppose it. The fundamental business of such a Council would be to bring together existing knowledge and disseminate it properly, to co-ordinate present investigations, and to map out future research. Under the first of these heads, it may be remarked, one of the most important tasks is to forward that knowledge directly to those who have to control, on behalf of the community, the country's food policy. General educational propaganda can probably best be left to other bodies, especially to those more closely linked with local government activities, a procedure that is rapidly extending in both Canada and the United States. One letter in *The Times* argues that the suggested work of a Nutrition Council is the function of the Cabinet's Committee on Food Policy. Surely this is but a further instance of the confusion to which we have just referred—quite apart from the fact that this Committee is concerned with transmitting advice and information only in one direction, upwards, and has no part to play in the organization of actual research.

Thus, decisions on food policy are, as Sir John Orr has also emphasized, matters for Parliament and the Government. The Nutrition Council as such should have nothing to do directly with food policy, but indirectly it could vitally affect policy. Its task would be, by its contact with responsible Ministers and administrators, to make available to them as rapidly as possible those established results of nutritional research on which, and on which alone, a wise and lasting policy, one that makes for health in the national sphere and peace in the international sphere, must be based. The conditions of war, despite all its handicaps and horrors, make advances in nutritional knowledge more rapid in many directions even than those that have characterized the last three decades or so. The potentialities can only be exploited to the full if all available knowledge and skill, from many scientific disciplines, can be brought to bear with speed and efficiency. A properly constituted Nutrition Council would be a valuable, and may be an indispensable, means to this end.

EDUCATION AND LEADERSHIP IN THE WOMEN'S SERVICES

THE report of the Committee on Amenities and Welfare Conditions in the Three Women's Services* merits wide publicity. A thorough and searching inquiry provides the basis for a balanced and reassuring report which effectively disposes of the vague and sweeping charges of immorality. Some unpleasant experiences in the Services are frankly acknowledged, and the report shows no lack of constructive criticism or, on the other hand, of appreciation for what is and always has been good in the three Services.

Healthy realism and common sense pervade the report, which does not conceal the fact that mistakes in administration have been made, and that the biggest problem in the Women's Services, as elsewhere, is not that arising out of hardships or rough conditions, which are instinctively recognized as part and parcel of the War, but out of boredom in the non-operational units. There lies the main danger to morale both in the Services or in the civil population, and it is of the utmost importance that due attention should be given to this question at an early stage.

Taking the view that the essentials for welfare are definite minimum standards of accommodation, warmth, food, medical attention and hygiene; good leadership by efficient and understanding officers; full utilization of individual capacity so far as the exigencies of the Services permit; and encouragement from home and from the general public, the Committee, while not minimizing the part which the Services have to play, shows unmistakably that the public must bear some responsibility itself in this matter of welfare. The part which the officer can play is rightly stressed. An officer whose first care is her platoon or company can, by her zeal, unselfishness and good sense, make the roughest conditions acceptable, while if an officer is indifferent or unsympathetic, the tone deteriorates and complaints mount up even in the best and most modern of accommodation.

---

* Report of the Committee on Amenities and Welfare Conditions in the Three Women's Services. (Cmd. 6384.) Pp. 58. (London: H.M. Stationery Office, 1942.) 1s. net.

With much of the detail of this report scientific workers have little direct concern, though the sanity and foresight of many of its comments, for example, in regard to cooking and the raising of standards, and the recruitment of officers, are of at least passing interest, but the invigorating vision of opportunity which characterizes the sections of the report dealing with education and with the future gives these sections at least outstanding claims on their attention. The Committee frankly recognizes that the major problem which lies ahead of society is how to reconcile in a highly mechanized world the quality and free expression of the individual within the framework of the co-operative State. The middle path has to be found along which organization and individuality can walk together hand in hand, and though the Committee recognizes that in the three Services young women have been brought together, without distinction of class, to share a common life while fulfilling a common duty to their country, it is felt that a great opportunity is being missed in another direction. Service life with its common tasks, common duties and common amusements is a training place in the subordination of the individual to the whole; but the whole can have no richness unless interpenetrated by the quality and variety of the individual human beings who compose it.

The mingling of all classes in the present national effort is unquestionably a situation full of promise for the future, and from this point of view the camps represent a great social experiment no less than a great military effort. Experiences previously unknown on one side or the other have been exchanged and shared. Camp life, too, is a great discipline in give and take, and in sharing the ups and downs of a common existence. From the soil thus ploughed a rich harvest may be gathered if the seed is first sown by a wise and skilful sower.

This is the point of view from which the Committee approaches the question of education, and while it is clear that so far as facilities and organization are concerned, the authorities provide generously for any educational demand made on them by the men and women of the Services, it is idle to pretend that the demand is in any respect equal to the possible supply. Education as a great adventure, as an adventure which makes life infinitely more attractive and exciting, is an appeal which falls too often on uncomprehending ears. It is a melancholy reflection, the report observes, on the educational failures of the last twenty-five years, that many young people refuse to use their minds at all outside working hours, and their only cry is for amusement which can be produced without any demand on their initiative, industry or intelligence.

The Committee considers that youth cannot be held responsible for this dangerous and disturbing position, which the difficulties of Service education in the present War have thrown into high relief. In pre-war days, leadership failed a young people who still depend more than they realize on the outlook of their elders, and who were left by the latter without any heroic appeal either to their imagination or sense of duty. We owe them what compensation in us lies for the state of the world as it is to-day, and the Committee refuses to acquiesce in a defeatist attitude about a matter so intimately concerned with the great issues of the present and future. A number of proposals for stimulating interest are made, the main recommendation being the appointment of an adequate number of women of suitable rank and relevant experience as education officers in the field to ascertain the outlook and requirements of the rank and file and to stimulate interest among the officers of the Women's Forces. It is recommended further that the curricula of the officers' training courses and of refresher courses should be placed on a broader basis; that the Army Bureau of Current Affairs scheme should be invariably applied in the A.T.S. and should be extended to the W.A.A.F. and the W.R.N.S.; that crafts should be encouraged for those whose tastes lie in practical directions, and that the Council for the Encouragement of Music and the Arts should be asked to co-operate in the general development of music, drama and the arts.

These recommendations are clearly to be justified on the ground of their immediate contribution to the morale and efficiency of the Women's Services. Their bearing on the welfare of the young womanhood of Great Britain after the War and on the future of the Women's Services, so brilliantly discussed in the concluding section of the report, is no less obvious. The unparalleled opportunity of education in citizenship and good living is recognized. There are things to unlearn and false idols to dethrone, but the chance if seized may sweep the whole national existence from banks and shallows into the great waters of the main.

Whether we look to this educational aspect or to the new riches which the country has found in this great development of skilled capacity in the Women's Services and elsewhere through the War, the question of the future of the Women's Services cannot but be considered. That indeed lay outside the terms of reference of the Markham Committee, though it is clear that the uncertainty is affecting the recruiting of young women of the professional classes. Moreover, no thoughtful observer can be blind to the waste which would be involved in any immediate break up of the Women's Services and the abrupt termination of their remarkable contribution when the cease fire sounds. Effort and sacrifice no less than time and worry went to their creation. Their efficiency increases daily, and it is only right that the question whether the State has no use for them after the War should be frankly faced.

Demobilization of a nation in arms and remobilization for the campaigns of peace should clearly, when the time comes, take place with due regard both to the tasks ahead and the personnel available. The Markham Committee is convinced that in the Women's Services the nation possesses an instrument of great potential usefulness, and suggests that when their present duties come to an end, their training and experience make them specially fitted for service in the field of European reconstruction. Detachments of the Women's Services would, they consider, be admirably fitted to share in the duties of the technical staffs which will be required throughout Europe, both for administration and relief, to meet the needs of the liberated populations. The various missions concerned with food and clothing, housing and medical assistance, which must clearly function as a first step on the Continent, for a time can obviously only function on a military basis and under the protection of the armed forces engaged in the restoration of order. Much of the work to be done is, moreover, work in which the co-operation of women is not only desirable but also essential, and that co-operation could be achieved rapidly and simply through the organization of the auxiliaries for foreign service.

Besides such specific duties as those of clerks, cooks, drivers and orderlies, there will be plenty of administrative tasks for officers capable of handling the problems of want and suffering which the liberated countries will present. While, however, employment for the time being on the Continent—for which, as the report notes, a precedent already exists—would ease the demobilization of the Women's Services and the return of its personnel to civil life, the Committee considers that the moral effect of this proposal is far more important than any other consideration. "To associate women with the task of reconstruction in Europe, to call upon them to share in a work of healing and mercy, would be not only to bring their war duties to a noble conclusion but to open a new chapter in international relationships of high value for the future."

There can be little doubt that volunteers would be forthcoming from all the Services for any feasible scheme on these lines, and that the auxiliaries would throw themselves into the work and adventure of peace with the same enthusiasm as they show to-day in the work and adventure of war. Knowledge and experience gained in this way could scarcely fail to be of value to themselves and others in remodelling a world in which all are groping towards some practical expression of the truth that we are members one of another, united by ties of past suffering and a larger hope for the future. There is wisdom as well as vision in these suggestions of the report, and they have their own special implications for all who are concerned with the wide problems of reconstruction, among which that of education adequate to meet the needs of a new world is one of the foremost and most urgent.

AUSTERITY THINKING

Sumner To-day

Selected Essays of William Graham Sumner, with Comments by American Leaders. Edited by Prof. Maurice R. Davie. Pp. xxvi+194. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1940.) 15*s*. 6*d*. net.

THE name of William Graham Sumner (1840–1910) is so comparatively little known in Great Britain, except perhaps as the author of "Folkways", that it comes as something of a surprise to discover that there is in the United States a Sumner Club which has sponsored the publication of this centenary volume "as a means for stimulating the scientific study of society". The book itself consists of reprints of some of Sumner's essays, lectures, and extracts from his works together with comments by so-called "American leaders".

The essays have as a whole an astringent flavour and are the more challenging as coming from the pen of one who was mistrustful of democracy in its hey-day, and a robust champion of the individualist point of view, a "hard-headed realist" as he has been called by a recent writer, "the father of all the debunkers". He tilts at what he considers the "absurd effort to make the world over", contending that the social order is fixed by laws of Nature which men must in the long run obey, their only hope of better and happier living lying in greater industry, self-denial and temperance. There is no short-cut to prosperity and no way by which men can be saved from the consequences of their own failure. He was disdainful of much of the teaching of his day: robust in his repudiation of many fashionable doctrines, and insistent above all on the necessity for dispassionate examination of social issues and problems and the separation of the scientific and emotional attitudes to these problems.

We have only recently entered upon a period in which it is possible for the sociologist to be educated as such, and Sumner went to Europe as a young man to study for the Christian ministry. From the Germans he apparently learned much through what he calls their "nobly scientific" approach to the study of the Bible. But at Oxford he gained more from his fellow students than from his teachers, and acquired such a taste for social and political inquiry that three years after his ordination in 1869 he was actually appointed to the chair of political and social science at Yale. There he wielded considerable influence, interesting his students in social study, taking over the Spencerian doctrine of social forces and social laws, and preaching the necessity both for studying and conforming to them. The word 'preaching' is used advisedly; for Sumner was nothing if not dogmatic, and (despite himself) as much moralist as scientist. There is little doubt, however, that he served a useful function in his day, shaking men out of their complacency, demanding careful scrutiny of measures proposed for the betterment of human affairs; pessimistic perhaps as to their consummation, but anxious only to know the truth—in the belief that the truth alone, however unpalatable, could set men free.

To Sumner, if the notion of equality was suspect, liberty as interpreted at the end of last century was no less so, and justice not by any means to be achieved along the lines of the panacea so frequently advocated —that of a fresh transfer of wealth from one section of the community to another. His plea for "The Forgotten Man", for example, is made in favour of the uncomplaining millions, the victims as he calls them of the reformer, the social speculator and the philanthropist—the small men of the lower middle class to whose misfortunes attention is seldom given, and who are called on from their meagre living to share the burden of the support of the socially inadequate. In a free democracy all propositions to do something for the working classes have, we are told, an air of patronage and superiority which are out of place; the capital needed for the support of social failures is inevitably diverted from alternative and better uses, and liberty must take the form of industrial competition.

Enough has perhaps been said to show the general tenor of the ideas set out in the papers collected in this book. The comments which follow them are brief, very variable in quality and character, and chiefly interesting as emphasizing the dual nature of Sumner's teaching: its 'timeliness' in the broader sense, its 'out-of-dateness' in many cases in the narrower. But when all is said and done the essays are still provocative and challenging and raise anew certain questions much in the minds of thinking men at the present time: how can we in fact embark upon a study of society that shall be truly scientific, for example, and to what extent can social planning be finally divorced from a consideration of the values involved? "The fashion of forming ideals", says Sumner severely, "corrupts the mind and injures character. What we need to practise, on the contrary, is to know with the greatest exactitude what is and then plan to deal with the case as it is by the most approved means." He demanded, in short, of the young men to whom he addressed the paper from which the above quotation is taken, an exercise in strict intellectual discipline which might well be emulated at a time when the practice of austerity in other fields has become for once both necessary and fashionable. E. I. Black.

BLUEPRINTS FOR A NEW SCIENCE

Foundations for a Science of Personality

By Dr. Andras Angyal. Pp. xii+398. (New York: The Commonwealth Fund; London: Oxford University Press, 1941.) 13*s*. 6*d*. net.

The title of this work might lead one to think that it deals with a branch of psychology. In point of fact, however, it is an attempt to define a science of which psychology as we now know it would be a branch. The other branches would include physiology, sociology, and indeed all the studies with the human organism and its activities. Dr. Angyal suggests that the time has come for a radical reconstruction of this group of sciences, not one of which can deal adequately with its subject-matter so long as it remains in comparative isolation from the others.

In attempting to assess the value of an ambitious work of this description there are two points that must be considered. First of all, are there good grounds for believing that such a reconstruction is necessary, or even desirable? In the second place, does the writer succeed in showing that the reconstruction which he advocates is possible?

Dr. Angyal establishes the first point without much difficulty. There can be no doubt that the various branches of psychology present to-day an appearance of almost complete disorder. Indeed, it might be said that there is no psychology but only psychologies. So that it is most refreshing to meet with a resolute attempt to tackle the theoretical problems, even though the result may be yet another psychology. But the second point is the critical one. Dr. Angyal is not the first to attempt to unify this group of sciences, though his approach is a new one. Does he succeed in overcoming the difficulties which his predecessors failed to solve?

In our attempts to understand the world round about us we have hitherto had at our disposal two great instruments, language and mathematics. Language abstracts qualities and relations from the concrete mass of events, and by so doing enables us to discover structure and regularity. Mathematics specifies this structure in quantitative detail. Now Dr. Angyal would have us approach the concrete datum which we wish to understand, and, without abstracting or dividing, apprehend it in its original "wholeness". We should study the total human organism responding to a total environment. It will obviously be necessary for us to deal with partial aspects of this total situation at any given time; but when we do so we should consider, not parts merely, but parts of such and such a whole. In fact, Dr. Angyal is postulating not so much a new method as a new category, and therein lies the real objection to what is otherwise a very attractive programme. For we cannot simply by taking thought alter our existing categories. There is no need to adopt a Kantian point of view and claim that only certain categories are possible. It is enough to suggest that existing categories are embedded in our thought and language much more deeply than Dr. Angyal seems to realize. A quotation may serve to bring this out more clearly. "Biological tensions viewed from the subject as a point of reference are considered as drives. Viewing the same tensions from the object side one obtains something similar to what Kurt Lewin calls the 'field forces' or 'demand qualities' of environmental situations" (pp. 128–29). The rather clumsy periphrasis, "something similar to . . . 'field forces' or 'demand qualities' of environmental situations", shows the sort of difficulty likely to be met with. Dr. Angyal has been forced to express himself in terms of analogies with physical science or with the sort of descriptive analysis which he has already rejected. He is, moreover, unable to express the "wholeness" of the situation directly, but has instead to move rapidly backwards and forwards between the subjective and the objective sides.

Dr. Angyal is by no means unconscious of these difficulties, though he may not realize how fundamental they are. "Relational thinking", he admits, "is so firmly rooted a habit that the transition to system thinking is at least as difficult as the transition from a three-dimensional to a four-dimensional geometry" (p. 261). The point is, however, that given an instrument, the transition presents no difficulty. What is difficult, if not impossible, is to express four-dimensional geometry in terms of our immediate apprehension of three-dimensional space. This seems to be equivalent to the task which Dr. Angyal has set himself.

But it would be unjust to suggest that Dr. Angyal is merely attempting an impossible task. What he has done is to raise issues of a very fundamental kind, and to make a number of very stimulating suggestions. His basic principles are probably correct. We should treat the problem of human behaviour as he suggests. Unfortunately, it seems doubtful whether we can at present do so. But this does not mean that we can never overcome our present limitations, and Dr. Angyal's re-orientation may in time develop a vocabulary and set of operations suitable to its requirements.

In any event, Dr. Angyal's work is a very timely survey of the psychological wood, when so many psychologists refuse to look beyond the nearest tree. Some of them may produce useful logs, others may do no more than carve their initials on the bark; but unless they can fit their activities into a wider whole their work is likely to have only accidental value. J. Drever.

NEW METALS AND NEW METHODS*

By DR. C. H. DESCH, F.R.S.

THERE has been an enormous increase in the production of the most important metals, the output doubling itself in quite a short period: twelve years for copper, seventeen for pig iron, eighteen for tin, and so on. Along with this quantitative growth, the development of modern industry has brought with it remarkable qualitative changes, elements which until lately were curiosities of the laboratory rising into industrial importance. Aluminium, which seventy-five years ago had only been obtained in quantities of a few pounds, had a world production at the beginning of the War approaching a million tons, while its later development on both sides of the Atlantic has been on a very large scale. Aluminium is not one of the rare metals; it is, in fact, the most abundant of all metals in the earth's crust, but at present bauxite, a rich mineral of very local distribution, is alone used for its extraction. But elements of rare occurrence, such as tungsten, molybdenum and vanadium, now occupy, in consequence of the ever-increasing demands of the engineering industries for materials of higher strength or other special properties, a key position out of all proportion to their abundance. This is largely due to the discovery that the properties of a metal may be profoundly altered by very small additions of another element, metal or non-metal. Pure iron is even softer than copper, but less than 1 per cent of carbon converts it into steel which may be made so hard as to scratch glass. This fact had been discovered empirically many centuries ago, but now that the process is better understood there are many other instances of the same kind. Copper can be made hard enough to serve as springs and even as non-sparking mining tools by adding 2·5 per cent of beryllium, while the soft metal lead may be strengthened, so as to offer a greater resistance to frost when used for water-pipes, by alloying with so little as 0·05 per cent of tellurium.

These and similar observations have led to important developments in metallurgy depending on the use of comparatively rare metals which are mostly found only in local concentrations in various parts of the earth. In a statistical table, the production of some of the minerals from which these rare elements are obtained may not seem impressive, but the access to them may be an important factor in the capacity of a country to produce machinery and other constructions into which metals enter.

The usefulness of the less common metals is, of course, not confined to small additions. The possible combinations of metals with one another are virtually infinite, and in spite of the vast amount of research and practical experience in this field, there must be many valuable combinations as yet undiscovered. The first recognition, partly accidental, that steel could be made to resist corrosion by incorporating 14 per cent or so of chromium, led to the development of the important class of stainless steels, while the new magnet steels, containing aluminium and nickel, and in their later forms also cobalt and copper, have brought about a revolution in the construction of electrical instruments and loud-speakers, the very high magnetic concentration which is possible with them enabling very small permanent magnets to be used. For other purposes, such as the clutches used for holding work in milling and grinding machines, they replace electro-magnets. With these steels it is possible to realize the image of Mahomet's coffin—heavy bars floating in the air in consequence of their strong magnetic repulsion.

A few of the rare metals find applications depending on their own peculiar properties. Thus tungsten, with its very high melting point of 3650° C., has superseded all other materials for the filaments of electric lamps. The invention of the fountain-pen called for an exceedingly hard and incorrodible substance for the tips of the gold nibs, and this was found in a native alloy of osmium and iridium. Tantalum has proved specially suitable for the spinnerets used in making artificial silk, rhodium and indium for depositing in thin layers on other metals for protection against corrosion, and so on. The non-metal selenium is used in photo-electric cells. Further uses of this kind will present themselves as the properties of the less common elements are studied more completely.

The high melting point of some of the metals has led to research in two main directions. On one hand, it has been necessary to devise means of making metals compact and strong without melting them; and on the other, to develop new materials and new techniques for operations at temperatures higher than those in ordinary metallurgical furnaces. Tungsten cannot be melted in a container of any known refractory material. The powder obtained by reducing its oxide is therefore packed into the form of bars under pressure and heated electrically until the particles cohere, and is then hammered in a special way until its strength is sufficient to allow of it being forged or drawn into wire. The same process has been applied to other metals, and a new branch of technology, known as 'powder metallurgy', has grown up. Not only the metals of high melting point, but also copper, bronze, and even the low-melting alloys of tin, are prepared in the form of small particles and made to cohere by heat and pressure.

The method has several advantages. Small objects may be produced of accurate shape, requiring no machining, by pressing in dies, while the mass may be made completely solid or given any required degree of porosity. Such porous masses are particularly useful for bearing metals, the spongy metal holding the lubricant better than by any arrangement of grooves. The method of consolidating a powder is also used in the making of carbide tools. Certain very hard compounds, especially the carbides of tungsten and titanium, which for many purposes can replace diamonds, are brittle in the mass, but if crushed and mixed with a metallic powder, mainly cobalt, and then heated until perfect union with the binding material is brought about, yield a composite mass which is excellent for tools and dies.

The chief obstacle to chemical operations at very high temperatures, 1,600° C. or above, lies in the difficulty of finding materials for furnace construction and for containing vessels which are both strong and resistant to chemical attack at such temperatures. The ordinary fireclays become soft and are attacked by slags. A few oxides, especially alumina, magnesia, thoria, and beryllia, meet severe requirements in this field, but their refractory qualities are lessened by quite small proportions of impurity, and their preparation calls for special technique, which has been developed as a result of long research in the laboratory, but has as yet been little applied on a large scale. When such materials become available in quantity—and there is no difficulty in principle, although the procedure may be costly—we shall see important developments in chemistry and metallurgy at high temperatures. It is interesting to note that it is the oxides of some of the rare elements—thorium, beryllium and zirconium—which have the highest softening points among the refractory materials, so that their importance will grow with the extension of high-temperature processes.

---

* Paper read at the Conference on Mineral Resources and the Atlantic Charter arranged by the Division for the Social and International Relations of Science of the British Association on July 25.

In the heating of metals or other conductors, it is not necessary that the heat should pass through the walls of the containing vessel, as it does when a metal is melted in a crucible furnace. Modern heating by induced currents of high frequency allows the heat to be generated where it is required; that is, within the mass to be heated. This involves a less severe tax on the refractory materials, and also makes it possible to enclose the charge in an outer closed vessel which remains cold, so that the operation can be carried out in a high vacuum or in an atmosphere of some inert gas. This is not merely a laboratory device, but is used on a large scale in a number of manufacturing operations, which will become more numerous in the future. Melting in a vacuum, out of contact with furnace gases, gives a means of preparing many substances in a state of great purity and soundness, unobtainable in other ways, and is already applied to certain alloys in amounts of several tons at a time.

Many chemical reactions are made possible or are accelerated by high pressures. The autoclave has long been a familiar piece of chemical plant, but some of the processes for the production of ammonia from the air or for the hydrogenation of coal to form oils and petrol called for higher pressures than those of the usual autoclave, and recent work, especially in the United States, has shown the remarkable results which may be obtained under pressures of many thousands of atmospheres. To construct vessels to be operated at such pressures, sometimes combined with high temperatures, naturally involves entirely new engineering methods. The materials used are mainly steels, although hard carbides may have to be used for certain parts; but for the highest pressures counterbalancing stresses have to be applied by shrinking one cylinder over another or in various ways producing an internal stress opposite to that which will arise in operation. Here is another new branch of engineering of great scientific interest, extending the range of usefulness of known materials.

The substitution of one metal for another for particular purposes is not always due to inherent advantages, but is often a consequence of a policy of self-sufficiency adopted by an industrial country. This motive has been very prominent in recent years. It is natural that Germany, producing much aluminium but very little copper, should adopt the lighter metal for overhead electric power cables, but a similar replacement in the windings of motors and dynamos was purely due to conditions of blockade and could not be defended on other grounds. During the period of armament and of hostilities such substitutions have been very numerous, but the subject is too big to be entered on here. A few instances of substitution under normal conditions may be mentioned. The saving of weight by using light alloys of aluminium or magnesium in place of steel has mainly been utilized in aircraft and rolling stock construction, but it has occasionally been applied in ordinary structural work. A bridge in Pittsburgh, having been condemned as insufficiently strong for the increased traffic, was lightened by replacing the wrought iron road girders and floor by aluminium alloy. The main girders were still in good condition, and the lightening of the dead load gave the bridge a new lease of life.

The substitution of one material for another is not, as a rule, a simple matter. Metals differ not only in strength but also in elastic properties, and this difference has to be allowed for. The new Quebec Bridge was designed to take advantage of the high tensile strength of nickel steel, the designers considering that the Forth Bridge, a very stable structure, was unnecessarily heavy. The disaster of 1907, when the unfinished bridge collapsed, was due to the crumpling of the lower members, although calculation had shown that the direct load-carrying capacity was ample. It has been proposed to use alloys of aluminium on a large scale in shipbuilding, their use in small vessels having proved successful, while the particular alloys used—those with magnesium—are highly resistant to corrosion by sea-water. In changing from steel to light alloy, however, it would not be enough to calculate the dimensions of each member to give a strength equal to that in a steel ship. The hull would float too high in the water, and problems of stiffness would arise from the very different elastic properties; to build a successful vessel the design would have to be new from the beginning.

So, when the hard carbide steels were introduced to take the place of tool steels for very heavy work or large output, allowing cuts to be made on a lathe at much higher speeds than before, advantage of the improved properties could not be taken until the machines themselves had been completely redesigned to allow of such high speeds without undue vibration; and in fact the introduction of carbide tools has meant a revolution in the machine tool industry, much plant intended for large outputs being rendered obsolete.

Three examples may be given of the substitution of an entirely new material for one of which the supplies have been found to be inadequate or too costly. Platinum, a metal of very local occurrence, has been largely replaced for chemical purposes, fused silica taking its place in the concentration of sulphuric acid, and iron oxide in various catalytic processes. On a larger scale, Chile nitrate, a product formed under quite exceptional climatic conditions and almost unique, is no longer indispensable as a fertilizer, the nitrogen compounds required for agriculture and explosives being obtained synthetically from the air. The third example is the introduction of plastics, resin-like substances which may be given the most varied properties. For many purposes they replace metals, and when reinforced by textile material or paper have a strength comparable with that of a metal. Transparent varieties replace glass and are far less brittle; other types take the place of porcelain and earthenware. The manufacture of plastics is one of the rapidly growing industries, and the uses of these new materials are continually being multiplied.

It must be realized that even such substitutions as these do not necessarily lessen our dependence on mineral resources, although the relative importance of different deposits may be altered. Nitrogen compounds are obtained by the use of electric power, which in some countries is derived from water, but in some of the most highly industrialized countries has to come from the combustion of coal. Many of the plastics are also derived from coal or petroleum, but being organic compounds, there is always the possibility of producing them from vegetable matter, as for example through the production of alcohol by fermentation and its conversion into more complex compounds. Such a procedure would be in line with the policy of depending on current revenue, derived from plants, rather than drawing unnecessarily on mineral capital, which once exhausted is not replaced.

Much might be said of means of economizing metals: the use of structures built up by welding, in place of heavy castings; the combination of concrete with steel in buildings and bridges; the saving of valuable metals by employing them as thin coatings on mild steel in chemical plant, and so on; but space does not permit. As new materials come into use and new techniques are developed, while at the same time the known reserves of some indispensable metals are being depleted, it becomes clear that the efficient use of the world's mineral resources demands systematic planning. First of all, a far more thorough world survey is needed, gathering together the information collected by prospectors in the interest of large industrial corporations as well as by the various national surveys. Such a survey would be the essential basis of any system of international control of mineral resources.

GROWING-POINTS IN THE STUDY OF GROWTH AND DEVELOPMENT

By DR. JOSEPH NEEDHAM, F.R.S.

EXPERIMENTAL morphology is a subject which has long suffered from the scattered nature of its publication mechanisms. The great series of the *Archiv. f. Entwicklungsmechanik* was at one time central, but is now, alas! no longer available, and though the American anatomical journals long offered a home for such studies, much of the work appeared in the proceedings of learned societies not always very accessible (for example, the Finnish contributions). Work on the borderlines of biochemistry and morphology, in particular, was widely scattered. Hence the need for some periodical publications of the regular conference type, to do for experimental morphology what the Cold Spring Harbor Symposia had begun to do so well for general physiology. The symposia now under review* are often referred to by the name of "Growth Supplements"; the correct description enshrining an auspicious pun. They will certainly stimulate the growth of our knowledge about growth and differentiation.

I had the good fortune to be present at the first two of these symposia. North Truro is a village lost among the sandy hills of Cape Cod, and there, in the spacious village schoolroom, under blue skies but with the shadow of war hanging over us, some hundred members met to discuss problems of experimental morphology. The proceedings were opened by an excellent account of the contributions of the explantation method by the veteran investigator, Warren N. Lewis. It is often forgotten that the discovery of the inductive action of the eye-cup on the presumptive lens tissue was discovered by him and Hans Spemann independently about the turn of the century, and that seven years later he narrowly missed finding that inductive action of the primary organizer itself which had to await the classical paper of Spemann and Hilde Mangold in 1924. Much of the rest of the North Truro symposium was, in fact, occupied by discussions of the present state of the organizer problem, in which valuable contributions were made by Paul Weiss. Arising out of Oscar Schotté's paper, considerable attention was given to the re-acquisition of competence by tissues undergoing regeneration, and the term 'recuperation' was proposed and adopted for this phenomenon. Curt Stern's paper was also very stimulating on the relation of genes and inductors. As regards growth proper, there was a good summary of the work on glutathione as a genetically controlled diffusible inductor working on body-size, by P. W. Gregory; and E. W. Sinott summarized his interesting investigations on the morphogenetic fields of the fruits of the Cucurbitaceæ.

The second symposium took place in the following summer at Salisbury Cove, Maine, and as there was not sufficient accommodation at the Marine Biological Station there for the meetings, we were kindly given the use of a charming wooden chapel in New England style, to which the members of the symposium were summoned by the ringing of the bell by the chairman. Here several brilliant summaries were given, particularly those by Douglas Whitaker on the mutual interactions of cells as exhibited in the early development of Fucus "eggs"; and by V. C. Twitty on the size-controlling factors in amphibian development, in which the complex questions of self-wise and neighbour-wise phenomena in growth of parts after transplantation and in physiological behaviour such as cardiac rhythm and pigment formation were lucidly described. H. Greene's account of the pathology of development, genetically produced abnormalities, etc., will also be found of much interest. For the biochemist, there was a brilliant account by the great physical chemist Freundlich (then at Wisconsin) of the colloid chemistry of development and growth, paying special attention to liquid crystalline phases in living cells, birefringence, importance of anisometric protein particles, etc. This article has also the melancholy interest of being the last which Herbert Freundlich wrote before his death. There was also an animated discussion of protein structure by O. L. Sponsler, well known as one of the earliest workers to apply the methods of X-ray crystallography to living structures (plant cell-walls).

The third symposium opened with an exceptionally important article by F. O. Schmitt on "protein patterns" in cells. This centred around the question of what it is exactly which happens to the cells of the presumptive neural tube in the embryo when, under the influence of the primary inductor, they

* First Symposium on Development and Growth, 1939; North Truro, Mass., ed. N. J. Berrill; contributions by W. H. Lewis, P. W. Gregory, C. Stern, C. H. Waddington, J. Needham, O. Glaser, O. E. Schotté, E. W. Sinott, J. H. Woodger; Supplement to *Growth*, vol. 3. Second Symposium on Development and Growth, 1940; Salisbury Cove, Maine; contributions by O. L. Sponsler, R. Schœnheimer, H. Freundlich, G. S. Avery, D. M. Whitaker, A. B. Dawson, V. C. Twitty, H. S. N. Greene, and F. S. C. Northrop. Supplement to *Growth*, vol. 4.

Third Symposium on Development and Growth, 1941; Hanover, New Hampshire; contributions by F. O. Schmitt, V. Tartar, K. B. Raper, A. F. Blakeslee, N. J. Berrill, A. H. Hersh, L. C. Dunn, and P. Weiss. Supplement to *Growth*, vol. 5.

All the Growth Symposia are obtainable as follows: by members of the Society for the Study of Development and Growth on application to Dr. J. W. Wilson, Biology Department, Brown University, Providence, R.I., U.S.A.; by non-members on application to the Editors of *Growth*, Dairy Building, Cornell University, Ithaca, N.Y., U.S.A. Prices: for members, vol. 1, 1 dollar, vols. 2 and 3, 2 dollars; for non-members, vol. 1, 2 dollars; vols. 2 and 3, 3 dollars.

change their shape by a profound elongation. While some workers are inclined to lay greatest emphasis on the existence of sub-microscopic anisometric protein micelles in the cytoplasm; while others suggest that the main factors are located in an ectoplasm similar to that which we know is responsible for the cell-shape changes in echinoderm egg cell-divisions; Schmitt and his colleagues direct attention rather to the cell-surface itself. The evidence for the 'zip-fastener' theory of neurulation must be read in the original, but it is sure that the time has come for an intensive attack on the cell surfaces by colloid chemists familiar with the properties of interfacial protein and lipo-protein monolayers. The recent fundamental work of J. Holtfreter on 'tissue affinities' in morphogenesis looks in the same direction.

Doubtless the most remarkable article in the third symposium is that of K. B. Raper on the developmental patterns in the simple slime-moulds. The facts there reported appear nothing short of amazing to the specialist in better-known fields of morphological study. Slime-moulds had indeed been coming into the limelight through the curious experiments of A. R. Moore on the ability of their protoplasm to pass through very fine filters, but its destruction if forced through much coarser filter pores. But now Raper describes for the benefit of biologists accustomed to less startling material how myriads of myxamœbæ of wholly different spore origin and initially equal potentialities come together in enormous numbers, integrate themselves into a co-operative functioning whole, and afterwards differentiate along specific lines within prescribed limits to produce a single fructification. The article is well illustrated with photographs and drawings showing how the myxamœbæ stream together towards a central mass or peg, which then lifts itself up and differentiates into a highly complex and specifically characteristic sorocarp. Congregations of myxamœbæ of different species move in to different centres. As if this behaviour were not enough, in some species the conjoined mass or "pseudoplasmodium" does a good deal of migration before it settles down and begins to differentiate. All these phenomena allow of much experimental analysis which has scarcely as yet been begun: the nature of the factors leading to aggregation, the mechanism of the movement of the pseudoplasmodia, and the factors governing differentiation of the sorocarp.

More familiar growth phenomena were not overlooked in the third symposium, however. A. F. Blakeslee gave a very interesting discussion of general growth patterns in plants, and heterogonic (allometric) growth problems in animals were well reviewed by A. H. Hersh. Finally, P. Weiss discussed the mechanics of nerve growth, dealing among other things with his 'deplantation' experiments, in which a piece of isolated nerve-cord and a detached limb are both implanted into the gelatinous connective tissue of the amphibian fin. Thus the gradual innervation of the limb and the spontaneous origination of rhythmical impulses from the nerve cord can be studied, as if in an elaborate form of tissue culture, subject only to the unavoidable endocrine environment of the host animal.

The above descriptions have not been able to do justice to more than a few of the admirable reviews in these symposia. By the time when this notice appears, the Fourth Symposium on Development and Growth, held at North Truro in August 1942, will be in course of publication. It was devoted to the general theme of the "Developmental Responses to Specific Chemical Agents" and included contributions by K. G. Stern on growth as a problem of chemical catalysis; E. L. Tatum on the relations between genes and growth hormones; E. J. Boell on the physiological and biochemical analysis of organizer action; P. R. White on developmental responses of isolated plant tissues; E. Allen on tissue growth and the sex hormones; F. C. McLean on ossification; O. A. Bessey on tissue responses to vitamin deficiencies; and A. J. Riker on pathological growth. It will certainly be as indispensable as the symposia which have preceded it.

If the present review serves to direct the attention of British experimental morphologists, in the widest sense of the term, to a series of conferences which are likely to remain for a long time the centre of these studies, and which, when the present troubles are over, may again unite biologists from both sides of the Atlantic, it will have achieved its purpose.

TEACHING OF COLOUR IN SCHOOLS

EDUCATIONAL reforms, large and small, are in the air. A great many people are taking advantage of the upheaval produced by the War to overhaul the existing educational machinery and to discover its weaknesses. Sometimes the material that is taught needs modernizing, sometimes it is the method of teaching that is wrong, sometimes there is a failure to arouse the latent interest and enthusiasm of a child in the fascinating natural phenomena that abound.

The subject of colour can occupy only a very small corner in the curriculum of school or university, but the phenomena of colour are so intimately woven into the pattern of human experience that what is taught is worthy of the best possible presentation. It is not an easy subject since there are too many avenues of approach—the physicist will want to start from the spectrum, the physiologist from the retina, the psychologist from the sensation, the artist from the point of view of beauty and harmony—but at least it is to be hoped that one teacher will not be in conflict with another.

It was no doubt partly from high academic motives such as these that the Physical Society Colour Group interested itself in the teaching of colour, but the Group also has its own problems which in part arise from the very diverse instruction on colour which members of the Group have received in earlier days. Some of these problems are concerned with terminology, which is anything but uniform; some are concerned with more fundamental matters, in which the principles accepted almost as axioms by one group of workers are neither understood nor accepted by other groups. Nothing would be more welcome to technical workers in colour than that their subject should be taught in a generally approved and consistent manner from the nursery upwards.

Co-ordination and combined operations are familiar phrases in these days and they might well be applied to the meeting arranged by the Colour Group on September 11 at the Imperial College of Science and Technology. Mr. E. G. Savage, education officer of the London County Council, gave a lecture with many demonstrations on "The Teaching of Colour in Schools" to an audience drawn from members of the Group, themselves representing a number of different colour interests, but augmented by members of the Science Masters' Association and of the National Society of Art Masters. It is a fortunate circumstance that a person in Mr. Savage's position is so intensely interested in colour, and the success of the meeting was in part due to the instructional value of the lecture and in part due to the many different suggestions advanced during the discussion for a more sympathetic alignment of the views of the scientific worker and the artist.

The greatest cause for dispute arises from the fact that the man of science, especially the physicist, deals primarily with the additive mixture of coloured lights, while the artist deals with the additive mixture of paints and pigments, which unfortunately acts as a subtractive mixture of lights. A yellow pigment is yellow because it absorbs blue light, and the more blue it absorbs, the yellower it becomes. A mixture of paints acquires its final colour through the absorption, or subtraction, of different parts of the spectrum in varying degrees by the component pigments. There is nothing very difficult to understand about this; yet the child is so accustomed from his earliest days to mixing, or adding, paints together, that he quite naturally considers that he is adding colours together; hence the results of colour mixing are conceived in terms of the results of paint mixing. This leads to a number of contradictions of which the most outstanding is the perennial argument as to whether yellow is or is not a primary colour. In passing, it may be mentioned that the argument is not made less complex by the just claim of the psychologist to regard yellow as a pure sensation. This, however, is another issue which must not be confused with the immediate problem concerning the mixture of lights and the mixture of pigments.

If we mean by 'primary colour' a colour that cannot be reproduced from the mixture of any other colours, then the physicist may with the greatest of ease show that he can produce yellow by adding red and green lights together. The artist, on the other hand, will show that he can produce green by mixing blue and yellow, but in no circumstances can he get yellow by mixing any other pair of paints. The artist may legitimately refer to yellow as a primary pigment; but he is in error in referring to it as a primary colour. There need be little difficulty in reconciling the two approaches, were it not for the fact that a child is used to handling paints from a very tender age, many years before he learns anything about the spectrum; when at last he does hear about the spectrum and its absorption, he will almost certainly have something to unlearn about colour and colour mixing. Perhaps the only solution to the problem is to introduce the spectrum to the student at as early an age as possible.

The spectrum was the centre piece in Mr. Savage's lecture. One of the first fallacies to be exploded is the not unreasonable assumption that white is the simple colour, while reds, greens and blues are more complex. Having shown that, physically, white light can be split up into its spectral components by means of a prism, it should next be explained why natural objects, such as grass, should be coloured. It is not sufficient, in fact it is incorrect, to state that the light reflected from the surface of the grass becomes coloured green. The light first has to penetrate into the grass, be absorbed inside the medium and the remnant reflected back from surfaces within the grass itself, before any colouring occurs. The light reflected from the front surface is uncoloured, as can be demonstrated by observing the images formed by reflexion in the front and back surfaces of a piece of coloured glass. This introduces the conception of absorption, which may be demonstrated without difficulty by projecting a spectrum on to a screen and inserting a number of colour filters into the beam in turn. Several interesting features then appear—such, for example, that a yellow filter does not merely transmit the yellow band in the spectrum, but in general transmits the whole of the red-yellow-green spectral region. Filters which show strong absorption are generally deep or saturated in colour, while those which show only slight absorption are desaturated or pale. In this way, by a series of experiments, it is possible to build up a general picture of the relation between the colours of objects as seen by the eye and the spectral composition of the light responsible for each colour.

When the physics of the problem has been grasped, it then becomes necessary to indicate that there are other factors at work; that what we see depends not only on the light sent out but also on the eye that receives the light. The effect of contrast, of adaptation, of after-images can be demonstrated without much trouble and indeed with very striking results, but to the young student these phenomena must undoubtedly appear as complicated factors of a somewhat baffling nature. This is surely the point where the art master and the science master should be particularly careful not to cause confusion by overstressing the subjective aspect of colour on one hand or the physics of the problem on the other.

There are many other aspects that can be considered: the effect of various types of illuminant, the possibility of reproducing any colour by the appropriate mixture of red, green and blue lights, the application of additive and subtractive mixture to colour photography and to colour printing, the formation of coloured shadows, and so on. If the subject is properly handled, it can be made an admirable medium for the teaching, not only of the facts of colour, but also of general scientific principles, and for the development of a healthy scientific curiosity. Why is the sky blue? Why do we get a muddy brown or grey when we mix all the paints in a paint box together? How do flowers get their colour? Perhaps even some history can be taught as well. It was mentioned, for example, that it was due to the influence of Chevreul that the French exhibit in the 1851 Exhibition outclassed the British, so far as colour and colour harmony were concerned.

It was very gratifying to find such a cordial spirit among the different interests represented at the meeting and to discover that each appeared willing and anxious to learn from the other. A mechanism for securing effective co-operation has still to be worked out; the question of a text-book is one problem, an agreed terminology is another. Mr. Savage has already contributed very greatly by the many lectures and demonstrations which he has given to groups of school teachers in various parts of Great Britain, and there is perhaps no better method of arriving at a consistent and acceptable doctrine of colour than through the missionary ardour he has revealed.

OBITUARIES

Prof. R. Willstätter, For.Mem.R.S.

THE death of Prof. R. Willstätter, which occurred at Muralto-Locarno, Switzerland, on August 3, a few days before his seventieth birthday, marks the passing of one of the great masters of organic chemistry.

Richard Willstätter was born at Karlsruhe on August 13, 1872, and received his early education at the Realgymnasium, Nürnberg. At the age of eighteen he entered the University of Munich, where he began his studies under Prof. Adolf von Baeyer. He remained at Munich until 1905, becoming while there *Privat-Docent* and then *extraordinarius* professor. In 1905 he was appointed professor at the Technische Hochschule, Zurich, where he remained for seven years. On the establishment of the Kaiser Wilhelm Gesellschaft laboratories at Dahlem in the suburbs of Berlin, he accepted the call there in 1912, holding the title of professor in the University of Berlin. On the death of von Baeyer he was appointed to succeed his old master at Munich. He remained in charge of the laboratories there until 1925 when, differing with the authorities on what he regarded as a matter of principle in university appointments, he resigned his chair. However, he was given facilities for work in his old department in a private laboratory, called after him the "Willstätter Laboratory", and there he continued, with assistance, his researches on enzymes. He seldom, however, visited this laboratory but directed the work mostly from his home in the Möhlstrasse. It was a source of special pleasure to him that his bust should be placed beside those of Liebig and von Baeyer in the corridor of the laboratories where he had been student and professor in turn. In 1939 he left his home in Munich, having narrowly escaped the concentration camp, and settled at L'Eremitaggio, Muralto-Locarno, where he lived the remainder of his life.

His wife died at an early age; his only son at the age of fifteen; he is survived by a daughter who is a mathematician and former pupil of Sommerfeld. He was awarded a Nobel Prize in 1920, and was a member of numerous learned academies and societies, including the Royal Society, the Royal Irish Academy and the Chemical Society. His portrait, in the series of "Scientific Worthies", appeared with the issue of NATURE of June 2, 1927, accompanied by an appreciative account of his work by the late Prof. H. E. Armstrong.

Very early in his career, Willstätter gave promise of great things to come. In the years 1893–94 there appeared six papers in conjunction with Einhorn on a variety of problems related to the alkaloids. His first independent publication dealt with the stability of ring systems, being a contribution to the 'strain theory' developed by von Baeyer. However, he developed at an early stage an interest in the constitution of the alkaloids and by a series of degradation experiments established the structural formulæ of cocaine and atropine, which he eventually synthesized in 1900–2. The latter work is detailed in 300 pages of the *Annalen*, a truly remarkable achievement on the part of the young scientific worker. He returned to the cocaine problem during the years of the War of 1914–18 and developed a technical synthesis on the lines of the classical work of Robinson.

The early years in Munich were also occupied with a variety of problems, among which were the production of *o*-benzoquinone, and various studies in catalysis. It was also towards the end of his first period at Munich that Willstätter began, with Stoll, his work on chlorophyll. On his translation to Zurich there began an intensive study of the natural colouring matters, principally chlorophyll and the carotenes. The nature of chlorophyll *A* and chlorophyll *B* was established, as was also the constitution of the chemically related blood-pigment hæmin. In the case of the carotenes, he established the highly unsaturated nature of these pigments, the structures of which were shown to be based on the isoprene unit. This period at Zurich was an extremely fruitful one in Willstätter's career, and the work on chlorophyll has been collected in a book written in conjunction with Stoll and published in 1913; this became known as "Das Chlorophyll-Buch". Gradually, Willstätter began to be interested in the biological significance of chlorophyll, and the results of this work, carried out largely in conjunction with Stoll during the Berlin period, appeared in 1918, over the names of the joint authors, as "Untersuchungen über die Assimilation der Kohlensaüre".

On going to Berlin in 1912, Willstätter entered on the second phase of his work on natural colouring matters. It was during his relatively short period there that he carried out his researches on the anthocyanins, the blue, violet and red pigments of fruits and flowers, in which he isolated the pigments in the pure condition as their salts, showed their glycosidic nature and their relationship to the yellow plant pigments, the flavonols. He established their constitutions and crowned the work by a synthesis of pelargonidin, the colour-base of the scarlet pelargonium. So complete was his survey of this field that, beyond hirsutin, found by Karrer in certain primulas, no significant addition has been made to the pigments isolated by Willstätter. In those days in Berlin it was pleasant to look out of the laboratory windows and to see the plots of poppies, dahlias, etc., which formed the raw material for his work, even though there was a sense of wasted effort when it was found that sufficient of the pigment of the dahlia could be isolated from a single bloom! It was during this period that he carried out his work on cellulose, while continuing research on chlorophyll and the alkaloids. Notwithstanding the success of his work, he did not regard his Berlin days as particularly happy, and no doubt the recent death of his wife helped to cast a shadow over this time.

With his return to Munich began the last phase of Willstätter's work. His earlier researches on chlorophyll marked his first encounter with enzymes, when he found that the phytol group of chlorophyll was removed in alcohol solution by chlorophyllase present in the plant. At Munich he began, with a brilliant band of collaborators, an intensive research on the isolation, reactions and constitution of enzymes. The results he collected and published in 1928 in two large volumes with the title "Untersuchungen über Enzyme". These volumes he dedicated to his life-long friend the late Prof. Fritz Haber.

When it is recollected that after the War of 1914–18 there was inevitably a period of delay before students were trained to the stage when they could become effective research workers, and when it is remembered that, in 1925, intensive research came to an end with his resignation from the University of Munich, the value and volume of work from Willstätter's laboratory during his short post-war period is astounding. This is not the place to recapitulate his contributions to enzyme chemistry; reference, however, may be made to the fact that he developed the technique, novel to this field, of selective adsorption in the preparation and separation of enzymes and expounded his theory of the active group associated with a colloidal carrier to explain their constitution. This work formed the subject of his Faraday Lecture given in London in 1927 and of the Willard Gibbs Medal address given at Chicago in 1933. After 1925 he continued to direct research, on a restricted scale, at the Willstätter Laboratory in the University of Munich, his principal collaborator being Dr. M. Rhodewald. What was probably his last publication appeared in 1940 in *Enzymologia*.

Willstätter liked it to be known to his friends abroad that, in the War of 1914–18, his sole contribution was of a humanitarian nature—he was the inventor of the three-layer protective filling of the German gas mask.

Though Willstätter is dead, he leaves behind him a band of former pupils who carry on his tradition in the academic and industrial spheres. There occur to one the names of Stoll, Kuhn, Waldschmidt-Leitz, Asahina, E. K. Bolton, Zechmeister, Forsén, Fourneau, Everest, Clarke, Page and a host of others all gathered together in that volume presented to him by grateful collaborators on his fiftieth birthday in Munich in 1922. The noble spirit that sacrificed itself for a principle, that declined invitations to work in other lands lest, in the acceptance, younger men might be deprived of their opportunities, is an abiding memory with all who had the good fortune to be reckoned among his friends.

THOMAS J. NOLAN.

Mr. F. W. Clifford

FELLOWS of the Chemical Society, and indeed all chemists who have occasion to use that Society's Library, must have learned with profound regret of the sudden death of the librarian, Mr. F. W. Clifford, at his home in Ealing on September 21. His illness in the early part of this year was a source of anxiety to his friends but he recovered and resumed his duties, and even a few days before his death seemed to be his normally cheerful and courageous self.

Clifford began his career in public libraries, first at Willesden Green and later at Hampstead, where he retained a connexion by evening work until 1903. He never lost his interest in this side of library work and was chairman of the Ealing Public Library Committee during 1923–27. In 1897 he accepted an invitation to become assistant librarian at University College, London, and, in the six years he spent there, gained valuable experience in the working of a large special library and himself contributed not a little to reforms in procedure. It was no doubt his experience and his efficiency in that position which led to his selection for the post which he was to hold with such success for the rest of his life.

When Clifford became librarian in 1903, the Chemical Society's Library contained about 15,000 volumes. The number is now about 45,000 and in peace-time is added to at the rate of nearly a thousand volumes a year. It was one of Clifford's greatest achievements that he contrived most ingenious methods of storing this huge accumulation of literature in the restricted space available in the Society's rooms at Burlington House.

Co-oerpation between British chemical societies began in 1919 and has now resulted, so far as the operations of the library are concerned, in the provision of a much wider range of technical chemical literature, a great extension of the clientele, and management by a Joint Library Committee on which all the associated and contributory societies are represented. Clifford rejoiced in these developments, and he and his staff worked loyally to promote them. As a result Great Britain now possesses what is probably the best chemical library in the world; it needs and has needed for years adequate housing.

Clifford was a member of many committees concerned with library matters. He provided written evidence for the report on Public Libraries in England and Wales presented to the Board of Education in 1927 and several of his suggestions were adopted in the report. He occasionally reviewed books on bibliographical subjects, and wrote a number of articles, of which one may be specially mentioned, "The Library of the Chemical Society: a Record of a Recent Attempt at Co-operation", published in the *Library Association Record* in 1919. He was a member of the Library Association and served on the council of the Association of Special Libraries and Information Bureaux during 1925–30.

Clifford never pretended to know the contents of chemical literature, but in knowledge of chemical publications of all kinds he probably had no equal. The story is told that on one occasion a candidate for a Ph.D. degree, persistently questioned by his examiner as to what literature he would consult in starting research on a new subject, quoted the usual German handbooks, dictionaries, etc., only to be met with the further inquiry, "And after that?", to which he provided the final answer, "I would then go to the Chemical Society's Library and consult Mr. Clifford." Clifford was always ready to give help of this kind and grudged neither time nor patience in his desire to be of service to inquirers. This kindness was based on a broad love of humanity as exemplified in his enthusiastic work for the St. John Ambulance Brigade, for which he did great service. For this he was made a 'serving brother' of the Order of St. John of Jerusalem in 1926, an officer of the Order in 1936 and in March of this year was given the rank of commander, a fitting tribute to a life spent unobtrusively in the service of his fellows.

T. A. HENRY.

Mr. B. M. Neville

MR. BERNARD M. NEVILLE, who died in April of this year at the age of fifty-five, was a schoolmaster whose outstanding abilities would have made a mark in any circumstances; but they were the more remarkable in view of the distressing disability which from childhood had stunted his growth but which had signally failed to check his enjoyment of life; he would have been the first to acknowledge how much it was due to the devotion of his mother that he refused to admit his physical limitations.

He was educated at William Ellis School, where he was physics master for more than thirty years, until his untimely death, and at Birkbeck College, of which he was a governor for twenty-four years. He was a Neil Arnott scholar of the University of London, and took his honours degree in physics in 1909. Later he became an associate of the Institute of Physics and a fellow of the Physical Society, and he was a prominent member of the Science Masters' Association, being a member of the Committee and for some years treasurer. He was a skilful experimenter, and his class demonstrations and lessons gave to many boys an enduring interest in science, and an appreciation of accuracy and general scientific technique which stood them in good stead whether they proceeded to more advanced scientific studies or turned to other pursuits.

His loss is mourned by many, to whom he was a patient teacher who spared no effort to help the willing, to whom he was a never-failing inspiration in the courage with which he faced an adversity that (in the words of another) "would have crushed the spirit and soured the nature of all but a very few", and above all, to whom he was a faithful and affectionate friend.

D. G. A. DYSON.

WE regret to announce the following deaths:

Prof. G. G. Henderson, F.R.S., emeritus professor of chemistry in the University of Glasgow, on September 28, aged eighty.

Prof. R. C. Robertson, professor of pathology and bacteriology in the University of Hong-Kong, on August 4, aged fifty-two.

Mr. E. T. Sandars, O.B.E., author of popular handbooks of natural history, on September 19, aged sixty-five.

Mr. A. R. Warnes, author of works on coal tar distillation and known for his special study of the restoration of stonework and ancient buildings, on August 25, aged sixty-four.

NEWS and VIEWS

Cultural and Scientific Mission in China

IN amplification of the note on this subject which appeared in NATURE of September 26, p. 369, Prof. E. R. Dodds, F.B.A., of the regius chair of Greek in the University of Oxford, will also be proceeding to China shortly on a mission of cultural co-operation, like Dr. J. Needham, F.R.S., on behalf of the British Council. In Chungking he will be attached to the Sino-British Cultural Association, and he will present letters of greeting to Academia Sinica (the National Academy of China) from the University of Oxford and the British Academy. Prof. Dodds will visit as many as possible of the Chinese universities and cultural institutions, and his stay will certainly do a very great deal to strengthen Sino-British cultural relations. It may be added that Dr. E. R. Hughes, reader in Chinese in the University of Oxford, has already been for nearly a year in China, at Kunming and other university towns, doing similar valuable work. The visit of Prof. Dodds and Dr. Needham was recently noted by the well-known Chinese newspaper, *Ta Kung Pao*, which published a leading article welcoming them in the warmest terms, and expressing the hope that the interchange of scientific workers and scholars between China and Britain may take place in the future on a much wider scale than hitherto.

Research and Research Workers in War-time

THE September number of the *Wireless Engineer* contains an editorial on "Research and Research Workers" with special reference to the demands of the present war effort. Under normal peace-time conditions, fundamental and applied research are carried on in one or more of three places: the colleges and universities; the various Government laboratories and those of research associations; and the research and development laboratories of industrial manufacturing companies. The demands of war render it necessary for the workers in these three groups of laboratories to intermingle to a considerable extent and to co-operate as a team in order that useful ideas may be built upon sound foundations and developed as rapidly as possible into practical technique and equipment which can be directly utilized by the Services. There is much controversy over the status of the research worker in the various institutions and laboratories, and the inadequacy of the supply of suitably trained workers with the right ability has given some of them an exaggerated view of their indispensability. On the other side, some industrialists not infrequently express their disappointment regarding the results of research as affecting their particular line of business. This is sometimes due to the lack of appreciation by the employer of the needs of the research worker, who cannot always produce results to order; there is on occasion a fault to be sought out and eliminated on the other side.

While the immediate needs of war tend to restrict long-term fundamental researches, it must be remembered that it is this type of research which in the long run yields the new developments in the commercial fields. But the greater intensity of, and the larger number of workers engaged in, applied research during a war period will undoubtedly pave the way for revolutionary developments afterwards. Thus the temporary sacrifice that the scientific investigator has to make at the present time, in abandoning the alluring search for truth for its own sake, is at least partly compensated by the knowledge that the diversion will in all probability yield things of great value when peace returns.

Universities of India

A VALUABLE survey of the work of the universities of India was given by Dewan Bahadur S. E. Runganadhan in a lecture before the India and Burma Section of the Royal Society of Arts on April 10 (*J. Roy. Soc. Arts*, Sept. 18). The paper gives a concise survey of the facilities for scientific research which have been developed in the last twenty-five years; a list of theses which have been accepted by Indian universities for the award of research degrees in recent years, which is appended, gives some idea of the standard of research work carried out in these universities. The subjects selected for special study under chemistry have a bearing on important economic plants, like jute, and Indian medical plants, and research on zoology includes valuable studies on parasites. The papers on botany indicate that there is considerable scope for the extension of research to more practical aspects of the plant life of India.

The importance of further co-ordination of university work in India is stressed, and the suggestion is made that some body corresponding with the University Grants Committee of Great

Britain, with a full-time chairman and secretary, should be constituted by the Central Government in India to advise on the distribution of funds available. Such a body would be in a position to give authoritative advice and guidance to the universities, without interfering with their economy, not only in regard to general expansion, but also as to the special lines of research they can most usefully undertake. There is a similar need for collaboration between the universities and various research institutions in the country, and particulars of some of the institutes which function as common federal institutions for advanced technical training and research are included in the paper. Some reference to the corporate life in the universities and the importance of continued contact between British and Indian universities both in regard to teaching, research and students is also included.

Tercentenary of the Calculating Machine

THE first calculating machine was invented in 1642 by Blaise Pascal. Had it not been for the War, the tercentenary of this event, which has had such a profound influence on applied mathematics and physics, would have been appropriately celebrated in Paris. In order that the date may not pass unnoticed, a small committee representing the Fighting French and British men of science, inventors and users has arranged a memorial luncheon to be held on October 19, at the Connaught Rooms, Great Queen Street, London, W.C.2, at 12.30 for 12.45 p.m. Prof. S. Chapman, president of the Royal Astronomical Society, will propose the toast of "Pascal—the inventor of the first calculating machine". The reply will be by Prof. R. Cassin, Commissaire National à la Justice et l'Instruction Publique. Other members of the Fighting French and French men of science in Great Britain will be present. Invitations are being sent to those who have been conspicuously associated with the development of calculating mechanisms, and to distinguished users of calculating machines, both scientific and industrial; tickets can be obtained from Miss M. E. Purves, 23 Bedford Square, London, W.C.1.

The luncheon will be followed by a small exhibition from 3 until 6 p.m. of calculating machines, with particular emphasis on models to show the actual mechanical working. A replica of the first machine made by Pascal will be exhibited and also a replica of the first calculating machine made in England by Samuel Morland in 1666. Demonstrators, in no way connected with the selling of machines, will explain the machines and models to visitors. Two 15-minute lectures have also been arranged, one at 3.30 by Dr. L. J. Comrie on "Mathematical Gymnastics with Calculating Machines", and the other at 4.30 by Mr. R. S. Nilsson on "A Description of Calculating Machine Mechanisms".

The British Astronomical Association

ON the invitation of the president and council of the Royal Astronomical Society, the British Astronomical Association is to be accommodated in future in the rooms of the former at Burlington House, London. Negotiations have been proceeding for some months and the final arrangements were completed in time for the British Astronomical Association to hold its first meeting in the new premises on September 30. A large part of the proceedings was devoted to a survey of the history of the Association since it was founded in 1890, special mention being made of its founder, Mr. Edward Walter Maunder. A number of members spoke about the progress of the Association during the fifty-two years of its existence and about the influence of many of its past members in shaping its policy and assisting with its remarkable development. It is worth noticing that the present international crisis has not affected its membership adversely—an indication of the interest which the amateur possesses in various astronomical branches. The new premises provide more adequate accommodation for the library and in other ways supply great facilities for the members, to whom the change has given considerable satisfaction.

Conference of Scientific Workers at Manchester

ON September 27, the North-West Area Committee of the Association of Scientific Workers arranged an all-day conference in Manchester on "Science and Total War". Opening the morning session, Prof. H. Levy asked the conference to consider the scientific effort of the country against the background of the slavery to which, literally, Hitler is subjecting the scientific workers and peoples of Europe. Total war demands total production at home, total production in the scientific sense. One of the biggest factors in ensuring total production, he said, are the production committees at which management and workers may overcome their traditional antagonism. Research must be centrally and co-operatively organized. The armed forces should select their officers scientifically and should ensure that there are sufficient technicians in the field to deal with problems as they arise.

Mrs. Barbara Ruheman described the contribution of science to the war-effort of the U.S.S.R., stressing the central position held by the Soviet Academy of Sciences in all Russian planning schemes. There is an intimate collaboration between the designer of a new fighter, for example, and the pilots who actually fly it. At the afternoon session difficulties arising in the working of production committees were discussed by speakers representing shop-stewards, engineers and chemists. These contacts were valuable in breaking down misunderstandings between workers and technicians. Resolutions were passed supporting the establishment of a whole-time central scientific and technical planning board, urging the strengthening of the Ministry of Supply's Synthetic Rubber Committee by the inclusion of technical experts, and the pooling of information, especially between firms engaged on medicinal research and production.

Biology and Control of the Bed-bug

THE Medical Research Council has recently issued in its Special Report series, No. 245, a "Report of the Committee on Bed-bug Infestation 1935–1940" (H.M. Stationery Office, 1942. 1*s.* net). It is in the form of a 64-page brochure which comprises six sections on the subject, concerned with the varied aspects of the problem, each being contributed by different specialists. In the section on new data bearing upon the ecology of the bed-bug, it is gathered that, provided a source of blood is available, temperature is the most important environmental factor. In unheated rooms the winter mortality of the bug population may be as high as 80 per cent, whereas in warmed rooms the population tends to increase enormously from year to year. The threshold of activity of the insect may be so low as 7–10° C., while a temperature of 13–14° C. is most favourable to a long life of the insect in the absence of food: both above and below this temperature life is definitely shorter at comparable humidities. For long life a high humidity is essential. At 45° C. (113° F.) the eggs succumb in one hour, and the adults in the same time at a temperature one degree lower.

As regards insecticidal methods of eradication, sulphur dioxide has proved to be a poor ovicide and not very toxic to the immature bed-bugs. An account is given of the circumstances leading to the abandonment of orthodichlorbenzene as a fumigant against the insect. Heavy naphtha is shown to be a useful contact insecticide, while its vapour action is particularly effective. The practical uses of hydrogen cyanide and heavy naphtha as fumigants have been investigated and conditions governing their application specified. Details are also given of the experimental methods used to test the effects of the insecticides employed on man. Of those investigated, orthodichlorbenzene is shown to be dangerous and heavy naphtha relatively safe. The concluding section is concerned with building design in relation to bed-bug infestation. It is stressed that new buildings should be so constructed as to provide the minimum harbourage for the insect and allow of its cheap and easy eradication in the event of infestation occurring.

Determining Colour in Telephone Cable

A METHOD is described by C. T. Wyman (*Bell Lab. Rec.*, **20**, No. 11, July 1942) of correctly determining the colour of conductor insulation papers, which, moreover, permits the use of a range of colours otherwise unobtainable. The system uses a scheme of colour notation developed in recent years by A. H. Munsell, in which each colour is specified by stating certain values for three parameters called 'hue', 'value' and 'chroma'.

'Hue' corresponds most nearly to what is normally called colour, five basic hues being used—red, yellow, green, blue and purple. Five intermediate colours—yellow-red, green-yellow, blue-green, purple-blue and red-purple—are also designated, and each of these ten hues is divided decimally to give ten sub-hues. Any hue is specified by a letter and a number from one to ten; thus 2*R* represents a red approaching the red-purple. 'Value' represents that characteristic most nearly described as 'lightness' or 'darkness', and is specified by a number from one to ten following the letter or letters designating 'hue'. 'Chroma' represents the degree of colour of any one hue, and is also represented by a number immediately following the 'value' number, but separated from it by an oblique line. A zero chroma would be a complete absence of colour, and would thus be a light or dark grey, depending on the value. A simple system of matching is thus available. It is not necessary to make samples of all the colours, however, because any colour may be obtained by mixing certain other colours.

In the method described several differently coloured disks are interleaved and the assembly is caused to rotate. The individual colours disappear and are replaced by a single colour corresponding to the particular combination. The Munsell Color Co. makes up a series of disks using light-fast dyes. These disks have a central hole to fit on the spindle of a motor, and a radial slit from rim to centre. A group of colour disks is selected which, when properly proportioned, will give the required colour, the disks being interleaved through the medium of the radial slots. The method has recently been adopted to secure colour standards for cable insulation, using a card carrying a peripheral scale mounted on the spindle behind the disks to provide a ready means of determining the percentage of each colour that is exposed.

Thickness of Aluminium Oxide Coatings

ALUMINIUM surfaces in telephone apparatus are sometimes protected by an electrochemically deposited oxide coating. It is important to control the thickness of these deposits and several methods have been tried. A majority of them, such as scratching the surface, stripping the deposit to weigh it, and measuring the thickness of a cross-sectional cut under the microscope involve destruction of the sample. A quick and reliable method, which is not subject to this limitation, is described in the *Bell Laboratory Record* of July 1942. It measures the voltage required to break down the oxide coating and punctures the specimen with so small a hole that it is not appreciably marred. A chromium-plated sphere about $\frac{1}{8}$ in. diameter is pressed against a thin plate of oxide-coated aluminium until the force, as indicated by a calibrated spring, is 1–2 kgm. Increasing voltages up to 1,500 are then applied, and that at which breakdown occurs is noted, the current being limited by resistors. This method has been used in the Bell Laboratories to study the relation between film thickness and the time to make the deposits electrochemically. The thickness obtained by an average of several readings is generally within ten per cent of the value found by direct measurement with a microscope.

Alcoholism and Crime

IN a recent paper (*Quart. J. Studies on Alcohol*, **2**, 686; 1942) Dr. Ralph S. Banay, chief psychiatrist to Sing Sing Prison, New York, records his experience of this subject based on detailed examinations, laboratory studies, social investigations and years of follow-up in confinement or supervision on parole. Statistical data showed that the principal difference between the alcoholic criminal and the non-alcoholic criminal was the high incidence of assault among the former, while in the latter crimes against property took precedence. This seemed to suggest that the primarily intemperate individual was drawn into crime not only for the need of money but also by the increased irritability, irascibility and pugnacity of the protracted alcoholic state. In conclusion, Dr. Banay deplores the fact that though a large number of all types of alcoholic offenders are passing through many corrective institutions throughout the United States, little is done for the study, understanding, prevention and treatment of them.

Dr. Wilhelm Camerer

DR. JOHANNES FRIEDRICH WILHELM CAMERER, an eminent physiologist and pædiatrician, was born at Stuttgart, the son of a well-known medical man, on October 17, 1842. After studying medicine at Tübingen and Vienna, he qualified in 1866 and for some years was engaged in private practice and public health work. Ill-health, however, compelled him to abandon these activities, and he devoted himself to scientific research at Urach in Würtemberg. His principal work was connected with metabolism in the child, on which he published a classic entitled "Der Stoffwechsel des Kindes von der Geburt bis zur Beendigung des Wachstums" in 1894, for which he was awarded the Niepel Prize. He also studied the metabolism in obesity, gout, diabetes mellitus and chronic renal and cardiac disease. In 1908 he contributed two important articles to Pfaundler and Schlossmann's "Diseases of Children" on "Metabolism and Nutrition in the First Year of Life" and "Children's Growth in Weight and Height". For some years he collaborated with Fechner, the experimental psychologist, in experiments on taste and touch. His interest in public health is shown by his papers on infant mortality and diphtheria. In recognition of his labours he was elected to an honorary doctorate of the Faculty of Natural Science of the University of Tübingen. He died on March 25, 1910.

ASLIB Conference, 1942

The Association of Special Libraries and Information Bureaux has arranged a conference to be held during November 7–8 in the rooms of the Royal Society. The preliminary programme includes an address by Sir Richard Gregory on "International Systems and Standards", a symposium on the use of microfilm, and papers on library training and on war-time books and periodicals. Most of the papers will be available in advance. It is also announced that discussion groups are to be formed in provincial centres, where those unable to attend the London conference can meet to discuss the papers presented.

The Nutrition Society

A whole-day conference of the Nutrition Society will be held at the London School of Hygiene, Keppel Street, London, W.C.1, on October 17, to discuss "Trace Elements in Relation to Health". Papers will be read by Dr. H. H. Green ("Significance of Trace Elements in Relation to Diseases of Plants and Animals"), Dr. R. L. Mitchell ("Distribution of Trace Elements in Soils and Grasses"), Prof. D. Keilin and Dr. T. Mann ("Copper, Zinc and other Trace Elements in relation to Physiological Function and Enzyme Systems"), Prof. T. Dalling ("Enzootic Ataxia or 'Swayback' of Lambs in England in relation to Copper Feeding of Ewes during Pregnancy"—film with running commentary), Sir Charles Martin ("Cobalt and other Trace Elements in relation to Disease in Australasia"), Dr. W. Lyle Stewart ("Sheep 'Pining' in Britain"), Dr. M. M. Murray ("Fluorine in Human Nutrition; *a*, Biochemical Aspects"), Dr. D. C. Wilson ("Fluorine in Human Nutrition; *b*, Clinical Appreciation of Fluorine Distribution"), Mr. F. H. Kemp ("Fluorine in Human Nutrition; *c*, Radiological Investigations"), Mr. F. Widdowson ("Absorption and Excretion of Trace Elements"). The chair will be taken at the morning session by Dr. J. Russell Greig, and at the afternoon session by Prof. C. R. Harington. Further details of the Nutrition Society can be obtained from the hon. secretary, Dr. Leslie Harris, Nutritional Laboratory, Cambridge.

Announcements

Sir Henry Dale, president of the Royal Society, has accepted the directorship of the Laboratories of the Royal Institution, with the Fullerian professorship, in succession to the late Sir William Bragg. Sir Henry has expressed the wish that his appointment should be limited to a period of three years, so that the managers of the Royal Institution may then be free to consider their future policy.

Dr. Dudley Stamp has been appointed adviser on rural land utilization to the Minister of Agriculture. Dr. Stamp is director of the Land Utilization Survey of Great Britain and was vice-chairman of the Scott Committee on the utilization of land in rural areas.

Dr. John F. J. Dippy, of the staff of Cardiff Technical College, has been appointed head of the Chemistry Department of Wigan and District Mining and Technical College, in succession to Dr. T. Heap, who has been appointed principal of Batley Technical College.

At the annual general meeting of the Physical Society held on October 2 the following officers were elected for the year 1942–43: *President*, Sir Charles Darwin; *New Vice-Presidents*, Prof. C. D. Ellis and Dr. H. T. Flint; *Honorary Treasurer*, Dr. C. C. Paterson; *Honorary Secretaries*, Mr. J. H. Awbery (Papers) and Dr. W. Jevons (Business); *Honorary Foreign Secretary*, Sir Owen Richardson; *Honorary Librarian*, Prof. L. C. Martin; *New Members of Council*, Mr. E. R. Davies, Dr. W. B. Mann, Mr. A. J. Philpot, Prof. H. C. Webster, Dr. W. D. Wright.

Lord Hirst of Witton, honorary member of the Institution of Electrical Engineers, has given £20,000 for the use of the Benevolent Fund of the Institution. It will be known as the Lord Hirst Fund to give assistance to applicants for help (or to their dependants) who have rendered important services to electrical science, or electrical industry or electrical engineering.

The Institute of Physics has arranged a discussion on the "Education and Training of Physicists", to be held at the Royal Institution on October 12. The discussion, which is to be in two sessions beginning at 10.30 a.m. and 2 p.m., will be based on the memorandum on the subject prepared by the Planning Committee of the Institute.

Already the Association of Scientific Workers has organized two conferences in London and two area conferences on the theme of "Science for Victory". A third area conference is to be held for South Wales at the Royal Hotel, Cardiff, on October 18. It will be in two sessions, beginning at 10 a.m. and 2.15 p.m. Five speakers lead each session, at the end of which there will be an hour for discussion. Abstracts may be obtained from the Association prior to the meeting.

The name of Dr. Wadie Tadros should have been included as a joint author with Dr. J. M. Robson and Prof. A. Schönberg of the letter entitled "A New Synthetic Œstrogen with Prolonged Action when Given Orally", published in Nature of July 5, p. 22. The omission arose through difficulties of rapid communication with Egypt.

Polyploid Inheritance in *Lythrum salicaria*

NEARLY thirty years ago attention was directed by N. Barlow[1] to the genetic problem presented by the inheritance of style length in the trimorphic heterostylic plant *Lythrum salicaria*. Barlow was able to show that the long-styled plants were true-breeding recessives, and that Short differed from Long and Mid plants in a single epistatic dominant factor. The hypostatic factor responsible for Mid style-length was shown to present anomalies, first in that homozygous Mids, giving, when crossed with Long, all-Mid progenies, were not found, and secondly, in the occurrence of progenies with four or more times as many Mids as Longs.

The theory of a simple hypostatic factor for Mid has been since revived by von Ubisch[2], without, however, offering any explanation of the anomalies to which attention had been directed by Barlow. In 1927, East[3], on the basis of extensive experiments confirming Barlow's facts, proposed that the Mid style was produced by either of two duplicate factors, which were both lethal when homozygous, one rather closely linked; so that the abnormal ratios might be produced by double heterozygotes carrying the two dominant genes in repulsion.

Two years ago[4], we published the results from reciprocal progenies obtained by interbreeding a Short plant carrying Mid, with a Mid daughter, obtained by crossing with Long. These two parents thus certainly carried the same Mid gene. Apart from Shorts, these critical progenies gave a good ratio of 3 Mids : 1 Long, and significantly contradicted the ratio 2 : 1 which would be expected from a lethal gene. We inferred that our Mid gene was certainly not lethal, and that some plants of these progenies, namely, one third of the Mids and one quarter of the Shorts, must have received the same gene from both parents. We suggested that the Mid : Long segregations observed by Barlow and East might be explained by the inheritance being polysomic[5], a possibility which is in full accord with the fact that *L. salicaria* has a chromosome number of 30, the basic number of the genus being 5.

Twelve of the Mid plants and sixteen of the Shorts were therefore crossed with Long, by open pollination, in 1941, and progenies from their seed have been grown this year. Plants which had received the Mid gene from neither parent would be expected to throw no Mid offspring; the expectation is that 4 of the Short plants should be of this type. Plants receiving the Mid gene from one parent only should give equal numbers of Mid and Long; 8 of the Shorts and 8 of the Mids were expected to fall into this class. Finally, plants receiving the Mid gene from both parents should throw no Longs if inheritance were simply disomic; they would be the homozygotes missing from Barlow's experiments. With simple tetrasomic inheritance, however, they should give 1 Long to 5 Mids, and with simple hexasomic inheritance (a possibility proposed to us by Darlington on cytological grounds) the ratio is 1 to 4. The distinction between the two kinds of polysomic inheritance is thus difficult to draw, but that inheritance is polysomic our experiments leave no doubt.

Table I gives the classification of the 16 progenies from Short-styled plants. There are 1,138 Short observed to 1,199 not Short, a small deficiency of Shorts, which is reassuring since any illegitimate pollination in this group would tend to give more than 50 per cent Short. The single Mid in the first line is thus probably due to stray pollen. A peculiarity noticeable this year, though certainly absent in 1940 and 1941, is that the Mid plants have flowered on the average before the Longs. Consequently, the excess of Mids among the families from simplex parents may be due to a number of Longs having failed to flower in their first year.

TABLE 1. PROGENIES FROM 16 SHORT-STYLED PLANTS

	L.	M.	S.	Total
Nulliplex, 1 family	70	1	77	148
Simplex, 11 families	396	458	795	1649
Duplex, 4 families	48	226	266	540

TABLE 2. PROGENIES FROM 12 MID-STYLED PLANTS

	L.	M.	S.	Total	Failed to flower
Simplex, 8 families	194	236	1	431	47
Duplex, 3 families	15	74	–	89	24
Triplex ? 1 family	—	41	–	41	8

Table 2 gives the classification of the twelve progenies from Mids. The single Short plant is certainly to be ascribed to stray pollen, which, as in previous years, has been of trifling frequency. The ratio Mid : Long is but little higher than for the Short progenies, which had grown well, whereas the Mid progenies suffered much seedling mortality. There is thus no reason to suspect illegitimate pollination as its cause.

The ratio Mid : Long in the duplex families is 4·708$\dot{3}$ in the families from Shorts, 4·9$\dot{3}$ in those from Mids. If adjusted for the disturbed ratio shown in the simplex families, these become 4·071 and 4·055. Taking both lots together, the adjusted value is 4·048. For what they are worth, therefore, these families favour the hexaploid ratio of 4 : 1 rather than the 5 : 1 appropriate to tetraploids.

The exceptional family may be plausibly interpreted as due to a triplex parent. Such a plant can arise from the fusion of a gamete carrying one Mid gene with another carrying two. Exceptional gametes of the latter kind are known to be produced occasionally as a result of the process termed double reduction, the exact frequency depending on the rate of crossing-over between the gene and the centromere, and the formation of multivalents, at meiosis. If inheritance is hexasomic, a triplex Mid is expected to give, on crossing to Long, at least one Long offspring in twenty; but with tetrasomic inheritance, Long progeny will be produced only rarely, by the same exceptional double reduction which originally gave rise to the triplex Mid. The present data are insufficient to decide between these segregations, being, in fact, in accord with both.

During the next three or four years we hope not only to investigate this exceptional plant, but also to continue our programme by building up plants known to be triplex, and testing their genetic behaviour. A fuller account of the researches to this year will be published in the *Annals of Eugenics*.

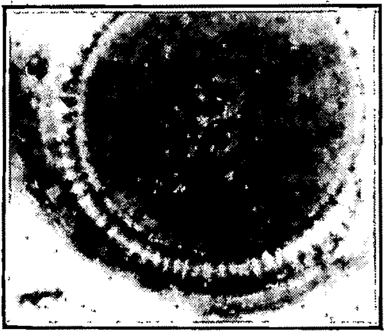
Genetic Classification of Brassica Crops

LAST May we were asked by Messrs. Carter whether there was any danger of intercrossing between kales and swedes. No precise information was available and classification by morphology offered little help for, as Bailey[1] remarks, the "*Brassica* group is indeed perplexing, excepting *Rubus* the most bewildering I have attempted". Indeed, in Brassica, we find it less confusing to use the English rather than the Latin names. To add to the confusion the kale concerned, Hungry Gap, was itself reputed to be a cross between widely different types. Therefore, we examined as many types of kale as we could obtain to find whether the chromosome number would throw any light on the situation.

Our results show that the kales are of two types, as follows:

	$2n = 38$	
Late Rape Kale	Hungry Gap Kale	Asparagus Kale
	$2n = 18$	
Dwarf Scotch Kale	Cottager's Kale	Perpetual Kale
Hearting Kale	Thousand-headed Kale	Marrow-stemmed Kale
Russian Kale	Curly Kale	Ragged Jack Kale

The swede has already been shown to be an allotetraploid, $2n = 38$, the result presumably of a cross between a cabbage type $2n = 18$, and the turnip $2n = 20$ [2,3]. We now see that three of the kales have the same chromosome number as the swede and they have no doubt originated by a process parallel to that of the swede, for example, by polyploidy following a cross between the 18 and 20 chromosome forms:



Pollen grain mitosis in Hungry Gap Kale showing haploid complement of 19 chromosomes

It may be concluded that the kales with 38 chromosomes will readily cross with each other and with swedes, while those with 18 chromosomes are only expected to cross readily among themselves and with cabbages, Brussels sprouts and other European forms of the 18 chromosome group.

Hitherto, the chromosome number in rape kale has been reported as $2n = 36$ [4]. As shown in the above table it is $2n = 38$. The swede rape also has the same number. The Hungry Gap kale is reputed to be a cross between late rape kale and curly kale. Since curly kale belongs to the diploid group it cannot well have been one of the parents. Hungry Gap must rather be derived from crossing within the tetraploid group.

Sulphanilamides and Experimental Tuberculosis

A NUMBER of workers have claimed that sulphanilamide[1], sulphapyridine[2], prontosil soluble[3], and sulphathiazole[4] in high concentrations may modify the course of experimental tuberculosis in guinea pigs. Promin, *p,p'*-diaminodiphenylsulphone-N,N'-didextrose sulphonate, has also been found effective in animal experiments[5]. However, no positive clinical results have been secured with the first-mentioned sulphanilamides, while promin is at present being tested.

It has been claimed that the lack of activity is perhaps partly due to the fact that the sulphanilamides used do not adequately penetrate the lipoid layer of the bacteria; and consequently an attempt has been made to achieve better results by introducing lipophilic radicals into the sulphanilamides. This theory appears reasonable, in view of the fact that *Mycob. tuberculosis* is an acid-fast bacillus rich in lipoids. On this basis, N^1-dodecanoylsulphanilamide has been prepared[6] and tested experimentally, without, however, consistent success[7,8]. Sulphanilamide derivatives of chalmoogric acid—of additional interest since this acid in itself has a certain activity against *Mycob. lepræ*, which is related to the tubercle bacillus—and of other lipophilic acids have also been prepared and tested in animal experiments against leprosy and tuberculosis, but without effect[8]. On the ground that sulphathiazole is considerably more active than sulphanilamide against most of the bacteria investigated, the introduction of a lipophilic substituent in the heterocyclic part of the first-mentioned compound has also been tried. A series of alkyl-sulphathiazoles[9] (amyl, heptyl, nonyl, etc.) as well as several alkyl sulphathiodiazoles[10] have been prepared in order to test them against the tubercle bacillus.

Thus, the results secured so far can scarcely be called uniform. Even if theoretically it would appear that lipoid-solubility should increase the contact between a chemotherapeutically active compound and the tubercle bacillus, this has not been proved. Furthermore, 'lipoid-solubility' is a comprehensive term, and in this case rather specific conditions may be involved. We therefore decided to attempt in other ways to obtain affinity for *Mycob. tuberculosis* while retaining the fat solubility.

The facts that *Mycob. tuberculosis* is able to form compounds of a vitamin K nature[11] and that the closely related *Mycob. paratuberculosis* (Johne's bacillus) requires such substances as growth factors[12], suggested an investigation of the chemotherapeutic effect of sulphanilamides which are substituted with naphthalene derivatives, of the same nature as the antihæmorrhagic compounds (vitamin K activity is found only in the series of 1,4-naphthoquinones or among compounds supposed to be convertible into such quinones in the organism; further, the effect is due to the methyl group at the 2-position; in the 3-position there must be no or only a certain kind of substitution[13]). We therefore synthesized a series of sulphanilamides which at the amido nitrogen, N^1, are substituted in this manner. The following examples may be mentioned: 2-sulphanilamido-1,4-naphthoquinone (1), melting point 227°; 2-methyl-1-sulphanilamidonaphthalene (2), melting point 248°; and 2-methyl-1-hydroxy-4-sulphanilamidonaphthalene (3), which melts with decomposition at 209°. (Further details will be published in the near future.)

The compounds, which are difficult to dissolve in water but more or less soluble in different fat solvents, possess lipophilic qualities in the wide sense of the term. They have been tested *in vitro*—in some cases *in vivo* also, due to the difficulty of dissolving them in water—against pneumococci of types I and III and against *E. coli* and have been compared with sulphanilamide and other compounds. All the compounds showed activity, particularly 1, which has a growth-inhibiting effect of the same magnitude as that of sulphapyridine. Experiments have been instituted to discover whether compounds of this type have any action on the tubercle bacillus. The synthesis of other similar compounds is also being attempted.

Since certain vital dyes have an affinity for *Mycob. tuberculosis*, we have started making substitutions in different sulphanilamides with groups which can be regarded as characteristic of the compounds showing this affinity. The substitution must, however, be done in such a way that the sulphanilamide derivatives fulfil the fundamental conditions for a chemotherapeutic effect. This should be feasible, since these conditions are now rather well understood. If it were possible at the same time—due to the substitution—to obtain an affinity, this might conceivably lead to a better contact. We intend to investigate this question.

The Golden Hamster as a Test Animal for Tubercular Infection

THE bacteriological diagnosis of specimens for presence of Koch's bacilli and testing of compounds for their antitubercular properties are mainly restricted to guinea pigs and rabbits; mice are naturally resistant to tuberculous infections, and lesions produced after injecting massive doses of tubercle cultures differ from those found in susceptible animals. We have now been able to confirm that the Syrian or golden hamster (*Cricetus* (*Mesocricetus*) *auratus* Waterhouse), after intramuscular or intraperitoneal infections with a human or a bovine strain, develops anatomical lesions similar to those seen in guinea pigs.

The lesions produced with doses as small as 0·001 mgm. of a virulent human strain have, after a period of 16–20 days, already developed sufficiently to give post-mortem findings (enlargement of lymphatic nodules close to the place of injection, enlargement of aortic and mesenteric glands, enlargement of spleen, miliary eruptions in liver, kidney and lungs) visible to the naked eye.

Hamsters thus offer considerable advantages in this type of experimental work. Besides being susceptible to infection with Koch's bacilli, they are small animals and are thus more economical of food and space than are rabbits or guinea pigs. Moreover, having an exceptionally short period of gestation and an average litter size similar to that of the rat (7–8 animals), a colony of adequate size can be built up more rapidly than can an equivalent colony of rabbits or guinea pigs; finally, the hamsters available in Great Britain, being highly inbred stock, have a genetic uniformity that makes them specially suitable for biological tests.

Viscosity and Chemical Constitution

SURFACE tension, σ, and viscosity, η, are regarded as manifestations of van der Waals' intermolecular forces of attraction. If, therefore, rise in temperature merely separates the molecules of a liquid, σ should be proportional to $\eta^{\frac{1}{2}}$, since σ is expressed in force units per cm. and η per cm.^{2}. This is approximately true for unassociated liquids over a considerable temperature range from the boiling point downwards.

Replacing $\sigma^{\frac{1}{4}}$ by $\eta^{\frac{1}{8}}$ in Sugden's parachor, gives $M\eta^{\frac{1}{8}}/D = \text{constant} = R$ (say), where M is the molecular weight and D the density. R is of the same order of constancy as the parachor over the above range of temperature and enables us to compare molar volumes of different substances at constant η. R is additive and a constant fraction of the critical volume. Analogous isomerides yield identical values. R thus promises to be a useful instrument for studying the constitution of liquids. By analogy with parachor, the name rheochor (Gk. *rheos*, stream) is suggested. At a later date it is hoped to publish elsewhere a detailed application of this expression.

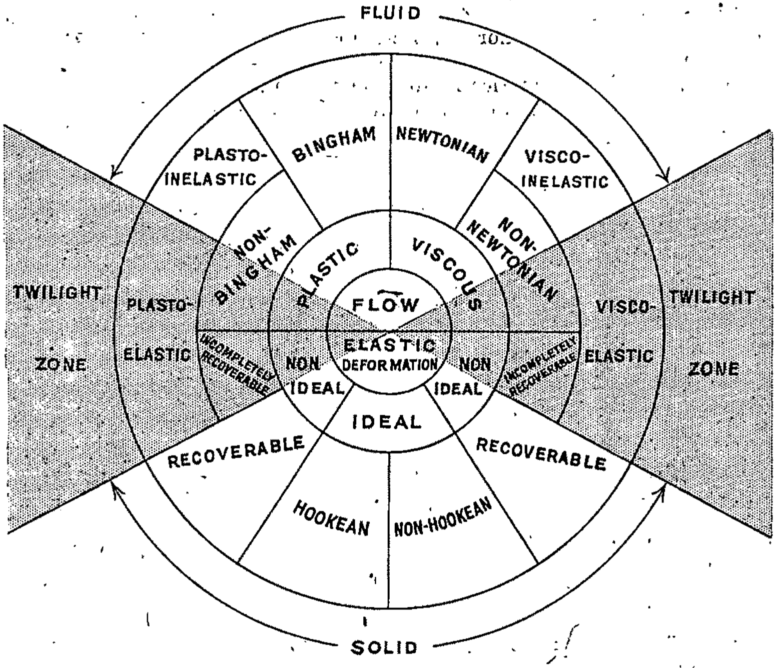
A Rheological Chart

FOLLOWING the classification of rheological properties discussed in NATURE of June 20, 1942, p. 702 the following chart is proposed. The chart, which is largely self-explanatory, is based on the scheme of classification proposed by Dr. Treloar and developed by Mr. D. C. Broome and the British Rheologists Club.

Starting in the centre of the chart the properties of matter are divided into the two major groups of flow and elastic deformation. Flow is divided into plastic and viscous types. Plastic flow is further divided into Bingham and non-Bingham, viscous flow into Newtonian and non-Newtonian. Non-Bingham flow is divided into plasto-inelastic and plasto-elastic, the latter overlapping the lower elastic half of the chart. Non-Newtonian flow is divided into visco-inelastic and visco-elastic, the latter also overlapping the lower half of the chart. There is thus seen to be an exact parallel between plastic and viscous properties in themselves and in their relation to the elastic properties of matter.



Elastic deformations are divided into ideal and on-ideal deformations, the latter appearing on both sides of the former in the chart. Ideal deformations are further divided into Hookean and non-Hookean. The non-ideal deformations are divided into recoverable and incompletely recoverable deformations, and the incompletely recoverable further divided into plasto-elastic, overlapping the plastic domain, and visco-elastic, overlapping the viscous domain. The coverable non-ideal elastic deformation is included vice merely to preserve the symmetry of the chart.

It is seen that the fluid properties of matter occupy he upper regions of the chart and the solid properties f matter the lower, while between them on either side a twilight zone exists where solid and fluid roperties subsist together. Ideal properties, therere, lie north and south and real ones east and est.

It is claimed that, whereas the proposed chart embodies no new knowledge, it expresses in a more vid and graphic manner than heretofore the interlation of rheological properties implied in the iginal scheme.

The Public Schools in Great Britain

READERS of NATURE at home and abroad should realize that the letter in the issue of September 19, p. 351, condemning public schools, and also the proposals to open them to boys whose parents cannot at present afford the fees, does not necessarily command the assent of a representative fraction of British scientific opinion. As one of those who did not sign the draft of this letter when circularized, I wish to disagree heartily with its tendentious political tone, which so distorts the aims, achievements and services rendered to the world, of our best public schools, as to present a grossly misleading picture which is likely to bring a valuable feature of British education into discredit with those who have not access to first-hand information.

I have very good reason to know that in the best public schools education is, both in scholarship and in character training, at least as good as anything to be found elsewhere in Great Britain and probably anywhere in the world; so good indeed that many of its features have been successfully adopted by secondary schools here, and by some schools abroad. During my time at one of the best-known, of these schools, though there were few specialists in science, teaching in these subjects was adequate and varied; and in mathematics it was excellent; while the range of reading and excellence of scholarship required of classical boys constituted a broad education such as can be found only very rarely in any country. Though my brother and I had our fees entirely remitted for some years, the idea of our being in any sense in the position of the "poor relation in the family of the rich", or "hostages" to perpetuate the unfair privileges of the wealthy classes, would have seemed so absurd as to merit no attention whatever. The tradition taught was never one of claiming privileges, but of fine scholarship and unselfish service to the community; and these traditions are well maintained at the present time, while the scientific education has improved until it is not excelled anywhere.

I object most strongly to the assertion that the social conscience of public school men is so warped that even their science tends to become an "esoteric cult". The record of achievement, in pure and applied science, of men from public schools, easily discovered by those who take the trouble to consult both scientific journals and such publications as "Who's Who", is very high indeed, despite the fact that until fairly recently the proportion of public school boys taking science seriously was not large. Neither is there any serious lack of good fellowship, nor class distinction, between those scientific men who were at public schools and those who were not.

The fact that the best of these schools produce a larger proportion of leaders in a great many departments of human activity than other types of school is due more to the excellence of the education they afford than to the special privileges of wealth or social position possessed by those who attend these schools. In the absence of prejudgment on the basis of a political creed which seems to regard income levels as the preponderant factor in classifying human beings, and automatically condemns as iniquitous those classes who start with a slightly higher income than others, the natural conclusion to be drawn from the success of men from these schools is that the schools are the best in the country, and is a good reason for continuing and even extending them. It is extremely foolish to begin reform of education by abolishing that type of school which, though not perfect, is at least as good as, and in some ways better than, any other.

It is unfortunately true that entry to public schools is almost entirely restricted to boys in the higher levels of family income, at present. This undemocratic feature has not been present throughout the entire history of these schools, and does not seem to be an essential feature of them. The admission of boys from elementary schools seems the right way to correct this fault. At present, there are considerable difficulties in the transition, partly because the boys destined for secondary education are drawn off from elementary schools some two years before the present normal age of entry to public schools, and the curricula of elementary schools do not lead naturally to those of public schools. These administrative difficulties should not be insuperable, with goodwill on both sides.

It is some decades since Oxford and Cambridge opened their doors widely to boys from all types of school, so that the society in universities is far more democratic than fifty years ago. This has not produced the "psychological dislocation" which the signatories to this letter anticipate; why should mixing of all classes of boys at school age produce this mental disease? It does not, in other countries where boys of all classes mix at school, and should not do so even in our ancient, or modern, public schools. The founders of our oldest public schools did not intend them to be reserved for the wealthy; and there is surely not so much difference in the nature of the boys from poorer and from richer families that they cannot mix! I suspect that what the signatories to this letter really fear is not the effect on the minds of the boys, but the imperilling of the creed that the interests of the richer and poorer classes must for ever clash. I welcome the attempts to throw open our best public schools to boys of all degrees of wealth, both as fulfilling the original intentions of the founders of these schools, and as an important step to the abolition of class distinctions.

Private Schools in America

THE letter on "The Public Schools in Great Britain" (NATURE, Sept. 19, p. 351), in its references to the system in America, does not show much acquaintance with the American scene.

There are in America half a million pupils in private schools—schools maintained solely by fees and endowments. Even allowing for a population in America three times that of Britain, one may say that this figure of half a million represents proportionately a private-school enrolment in America at least twice as large as the public-school enrolment in Britain.

In neither country, I submit, is the factor of wealth so excluding, so all-pervading, as the signatories of that letter suggest it is in Britain. As in Great Britain numerous scholarships are open to pupils of small means, so they are in America.

An important aim of American private schools is to set a standard of manners—a thing difficult to preserve in an American pupil if he lives in a metropolitan area and has for years to attend a tax-supported school largely populated by children of immigrants. However, American private schools are not divorced from democracy. For example, many of them serve the community in which they are located by offering night courses for adults, or serve the nearest metropolitan district by operating summer camps for city children. In both these activities the senior private-school pupils themselves take part.

Science and Organization

I READ with much interest the leading article in NATURE of September 12 on the "Organization of Science for War". There are few scientific workers who will not agree with the need for careful planning, both for the conduct of the War and for the urgent problems which must be solved in the post-war years: so far from wishing to criticize this point of view, many have complained, as is noted, of the inadequacy of organization and of the failure to utilize their skill.

But while these views are almost universally held, I believe that many men of science will regret some of the references to those scientific workers who are convinced that there are other considerations of importance. It is unfortunate to suggest that scientists "have spent too much time squabbling among themselves over such questions as to what extent science should be planned", for surely such discussions have in fact occupied few scientists for very little time; in any event, "in the democracy for which we are fighting" we may anticipate that it will not be thought improper for scientific workers who recognize their duties to society to put forward views regarding the extent to which scientific research can advantageously be planned.

While convinced of the need for the planning o co-ordination of research both for the present and for the immediate future, I would suggest that any long-term plan must recognize that, in addition to a main body of directed investigators, there must be the largest possible number of 'free' researchers acting as pioneers in the opening of new spheres of work. For many reasons, it would be desirable tha much of this pioneer activity should be centred, as at present, in the universities.

In this connexion, too, it is to be hoped that those concerned with planning will not overlook the cultural aspects of science: unless art, music an poetry are to be frowned upon, there must surely b a place for scientific work for which no probable utilitarian value can be foreseen.

To many these views will probably be no mor than platitudes, but they are restated briefly in the hope that some confused issues may be clarified.

RESEARCH ITEMS

Marine Fauna of Bristol Channel

IN recent years some very useful information has been compiled from the vertebrate and invertebrate survey of the Bristol Channel which Prof. C. M. Yonge introduced about 1937 and has generally supervised. This biological survey covers chiefly the intertidal fauna of the Severn Estuary and Bristol Channel. Having previously listed fifty-four species of Amphipods, R. Bassindale has recently reviewed the distribution of these animals in the area (*J. Animal Ecol.*, May 1942), *Gammarus zaddachi* being the commonest, occurring in three forms, one of which extends to fresh water, and the salinity ranges of five species of Gammarus and Mariogammus are given and comparisons made with the Tay. Previously, Bassindale had listed (*Proc. Bristol Naturalists' Soc.*, 1940) 3 species of Protozoa, 10 Porifera, 88 Cœlenterata, 3 Platyhelminthes, 1 Nemertine, 1 Chætognath, 33 Annelids, 2 Gephyrea, 235 Arthropods, 134 Molluscs, 68 Polyzoa, 5 Echinodermata and 5 Tunicates, although many species remained to be determined. At the same time A. J. Lloyd listed 111 fishes, including the burbot, sandy ray, flying fish, seahorse and boarfish. L. H. Matthews added a list of 5 Pinnipedia (seals and walrus) and 11 Cetacea. Further notes on the fishes have been given (*Proc. Bristol Naturalists' Soc.*, 1941), and some corrections add the deep sea fish, *Marolicus muelleri* (Gmelin), which has luminous organs. The area covers the Devon, Somerset and Gloucestershire coasts from Ilfracombe to above Gloucester, and the expenses of the survey and publication have been borne by the Colston Research Fund of the University of Bristol. It makes an interesting comparison with the faunal survey of the littoral of the Isle of Man and the Lancashire, Cheshire and North Wales coast by the University of Liverpool biologists over a period of more than fifty years, the survey of the River Tees in 1935 (Tech. Pap. Water Pollut. Res., 5 and 6) and the work on the fauna of the Tamar estuary (*J. Marine Biol. Assoc.*, 23 and 24).

Biology of the Larch-Shoot Moth

BRYAN P. BEIRNE has contributed a paper on the biology and control of this insect, *Argyresthia lævigatella* (*Econ. Proc. Roy. Dublin Soc.*, 130–49; August, 1942). The adult is a small creature measuring 12 mm. across the expanded wings. It ranks as one of the chief enemies of the larch and causes a considerable amount of damage in many parts of Europe. The larva lives internally in the shoots, ultimately causing their death by eating into the wood. No artificial control method can be suggested apart from hand-picking of infested shoots—which would only be possible where the trees are young and few in number. The author concludes from an examination of infested shoots that 77 per cent had the contained larvæ destroyed by natural enemies. Of this percentage insectivorous birds account for 67 per cent, unknown causes 5 per cent, fungi 2 per cent, Nematoda 2 per cent, and Hymenopterous parasites 1 per cent. Of the last-named enemies only one species, the Ichneumonid *Ephialtes elegans*, was bred out, and an illustrated account of its life-cycle is given together with descriptions of the morphology of the early stages.

The Maize Shoot

A COMPREHENSIVE developmental study of the shoot of a complex monocotyledon, such as maize, requires special methods of technique, and in the present study, B. C. Sharman has supplemented the usual anatomical methods by processes of retting, plasmolysis and the utilization of special methods for fixation and staining of cytoplasmic details (*Ann. Bot.*, N.S. 6, 245; 1942). It is brought out very clearly that the growth is articulated, the unit consisting of lamina, sheath, internode, nodal plexus and either a ring of roots or a bud. Within each such unit the main and lateral strands are initiated basifugally, but numerous small strands undergo all their differentiation basipetally, as well as the last protoxylem and all the metaxylem and metaphloem of the main and lateral strands. Where such strands are differentiating in tissue outside their own unit, their development probably comes more under the control of conditions existing in the other unit. It is also evident that in maize, 'file' growth plays a very considerable part; though partially vacuolated, this type of tissue constitutes the so-called intercalary 'meristem' and, so long as not too far differentiated, the cells may return to the meristematic condition as new prodesmogen strands differentiate. The basipetal sequence of development at a time when the lamina is emerging into the light is suggestive that this process is associated with transfer of food materials down into the axis to supply basifugal prodesmogen differentiation of strands destined to run to new leaves forming above, as well as to supply the growth of roots and buds from the node at the base of the unit. These points as well as others, such as the occurrence of periclinal divisions in the dermatogen, the dermal nature of the ligule, the appearance of new strands from file meristem, the debated question of cambial activity in the bundles, etc., are discussed and amply illustrated by very clear line drawings, diagrams and photographs.

Artificial Culture of Plant Embryos

J. van Overbeek, M. E. Conklin and A. F. Blackeslee (*Amer. J. Bot.*, 29, 472; 1942) have had considerable success in culturing embryos of Datura from fruits ten days after pollination. They used dextrose, mineral salts, several physiologically active substances and coco-nut milk. An increase of 500–8,000 times the volume size was obtained in ten days. Viable seedlings could be obtained by transferring the embryos to a medium without coco-nut milk, which inhibits root production. Coco-nut milk contains at least three factors affecting the growth of the embryos: (1) a thermolabile factor controlling growth and differentiation, (2) a thermostable factor causing callus growth and no differentiation, (3) a thermostable factor which inhibits root growth. G. W. Skimm (*J. Hered.*, 33, 211; 1942) was similarly able to increase the viability of embryos in Prunus hybrids. In seventy-six crosses no seedlings were obtained by normal development but they were obtained by artificial cultures. In many other crosses the percentage of seeds which were germinated was considerably raised by artificial culture. Similar phenomena were found in Lilium hybrids. Artificial embryo-culturing largely overcomes the abortion which occurs at different stages of embryo development in hybrids.

Elastic Constants of Metal Crystals

A THEORETICAL treatment of the elastic constants of metal crystals is given by K. Fuchs and H. W. Peng (*Proc. Roy. Soc.*, A, 140, 451; 1942). The approximate equations of motion for the electrons in a cyclic lattice of a metal are set up with the help of the self-consistent field. The displacements of the ions are then considered as perturbations of the motions of the electrons. The change of the boundary is compensated by a co-ordinate transformation. The change of the potential energy of the lattice due to homogeneous deformation is calculated by the perturbation method. The calculated values of the elastic constants are found to be in satisfactory agreement with the observed values.

Dynamics of a Spinning Top

AT the meeting of the British Astronomical Association, held at Zion College on August 26, J. Miller showed some experiments with a spinning top which seemed to controvert the usually accepted views regarding the rising of tops (*J. Brit. Astro. Assoc.*, **52**, 250; Sept. 8, 1942). It is laid down as a principle in text-books that, if the precession is hurried up, the top rises—a principle with which Miller agreed—but he traversed the additional law that friction is responsible for hurrying on the precession. He showed an electric motor, specially designed by him for experiments with rotating bodies, in which the vertical axis of a rapidly rotating spindle is hollowed in such a way that the toe of a top can rest in it while spinning. When the spindle is made to rotate by an electric drive, and a top, which has been given a spin in the same sense as the rotating spindle, but with a smaller angular velocity, is placed on it, the top precesses just in the same way as it does when the current is cut off and the spindle is at rest. In accordance with the usually accepted view that the friction between the toe and the point of support is responsible for hurrying on the precession, there should have been an alteration in the sense of the precession, because frictional effects had been reversed in direction. Miller suggested that some of the mathematical theories should be subjected to crucial tests before they are accepted as explanations of various phenomena to which we have become accustomed, but for the exposition of which theory is sometimes at fault.

Rotating Sectors in Stellar Photometry

DONALD A. MACRAE discusses a new technique in photometry—a rotating sector (*Sky and Telescope*, August). In the accurate determination of the magnitudes of stars, it is important to be able to reduce a star's light by a known fraction, and this can be accomplished by placing in the beam a small disk from which a sector has been removed. When the disk is set rotating during exposure, the star's light is reduced in the ratio of the open to the solid part of the disk. A difficulty arises over the *reciprocity failure*, which implies that the emulsion does not react in the same way that it would to a constant light of the reduced intensity. Research in the laboratory has shown that the difficulty can be overcome by rotating the sector fast enough, and when the rotation rate exceeds 4,000 rev. an hour, the plate will react as it should. No systematic errors will arise in the 'magnitude scale' set up by this new method. L. F. Barcus, of the Sproul Observatory, shows the application of the rotating sector in another field. As is well known, the relative positions of two stars can be measured more accurately by photographic methods if they are nearly of the same brightness. As this is seldom the case, sectors are used to reduce the brightest star. Mr. Barcus describes the difficulties which must be overcome in cutting and mounting a set of sectors giving reduction factors from a few tenths to several magnitudes.

Cyanogen Criterion of Absolute Magnitude

CYANOGEN is a common constituent in interstellar space, in comets and in the atmospheres of some stars. The true luminosity or absolute magnitude of stars having temperatures comparable to that of our sun has been found from the apparent conspicuousness of cyanogen in their spectra, but the results have not always proved reliable. Dorrit Hoffleit, at Harvard, has recently utilized new available material on the proper motions of the stars to test the validity of the application by F. Becker of the cyanogen criterion to stars in the −45° zone (*Sky and Telescope*, August). He found that accurate measurements of cyanogen line intensities on standardized plates of good quality yield absolute magnitudes superior to estimates based on spectral class alone. On the other hand, simple eye estimates on unstandardized objective-prism plates of faint stars are not necessarily adequate in determining whether a star is of high luminosity. Stars identified by Becker as giants are practically always true giants, but those provisionally assumed to be dwarfs are often erroneously classified as such, according to Dr. Hoffleit.

Orbital Variable Stars

IN a paper with this title (*J. Brit. Astro. Assoc.*, **52**, Sept. 8, 1942), P. M. Ryves deals with a number of divisions under which orbital variable stars may be included. Tidal effect is a factor which arises out of the close proximity of two stars. Gravity acting on the surface of the companion is responsible for a disturbance which implies greater brightness on the nearer portion, and each star will appear to vary in a period equal to that of the revolution, unless they are viewed from the pole of the orbit. If the components are equal, the variations will cancel out, but if they are unequal the tidal effect shows up in the light-curve. Another way in which a binary may appear to vary is through the effect of the radiation of one star on the other, and this may be greatly enhanced when the components are close. While there are no cases of stars varying from radiation effect alone, it is possible that some may be discovered by future research among spectroscopic binaries. Another way in which variation of light occurs is due to ellipticity, and a few such stars have been detected. A closely connected pair will be subjected to a strong gravitational field and will assume an ellipsoidal shape. In cases where they are viewed broadside on, they will present a larger surface and will send us more light than when they are seen end on. The light from such a pair will not vary intermittently, like Algol, but continuously, the period of light-variation being equal to half the revolution period. The character of the variation will be of the sine-curve variety, similar to a symmetrical Cepheid, like η Geminorum. Among the other classes may be noticed ellipticity combined with eclipse, and when such occurs we have the W Ursæ Majoris class if the components are equal, and the β Lyræ class if they are unequal. Under eclipses alone is included the well-known Algol class.

LOCATION OF INDUSTRY ON MERSEYSIDE

THE Social Science Department of the University of Liverpool continues to carry on its invaluable work in war-time, and in the latest volume in the New Merseyside Series, the Statistics Division has made an important contribution to the local planning which must be undertaken within the scope of national planning principle. "The Distribution of Population and the Location of Industry on Merseyside", by W. Smith (Liverpool: University Press of Liverpool. 5*s*. net.), gives a clear and carefully drawn picture of the industrial features of the area as they were on the eve of the War. Mr. Smith indicates the elements of change as well as of stability, and this admirable analysis of the industrial and social pattern of Merseyside should stimulate research workers in other areas to bring up to date, so far as possible, parallel investigations in their own areas, in order to provide the factual basis for any detailed attempt to plan the post-war location of industry.

Analysing first the distribution of population, Mr. Smith points out that differential age-composition may be dismissed as definitely not responsible for the higher birth-rate of Merseyside and that the population of Merseyside would grow naturally and continuously if no other factor intervened. Since 1927 the migration curve of Merseyside, which has consistently shown an annual net exodus, has varied with the state of trade in Britain, increasing when industry and trade have been active and falling away when they have been sluggish. In regard to the local distribution of population on Merseyside, Liverpool, Bootle and Birkenhead exhibit comparable trends. Bebington, Crosby, Hoylake, Ellesmere Port and Wirral all show, after adjustments have been made for changes in boundaries, continuous inward balances of migration, while Huyton and West Lancashire both exhibited an outward migration balance prior to the War of 1914–18. The core of Merseyside is an area of high natural increase but, since 1927, of large outward migration balance and of declining population, while the margin is an area of lower natural increase, in places of natural deficit, but of large inward migration balance and of increasing population.

In regard to the location of industry, Mr. Smith points out that throughout the period 1924–39 Merseyside had less than its share of employment and more than its share of unemployment, the gap tending to increase during the period up to 1937–38 and markedly decreasing in 1938. There was a substantial recovery in the employment position on Merseyside on the eve of the War, but insufficient to make good completely the ground lost in the preceding years. Analysing the industrial character of Merseyside, it is noted that metals and engineering, other manufacturing industries and 'other services' have fluctuated widely, and these groups occupy a relatively larger place in the economy of Merseyside in times of boom and a relatively smaller place in times of depression. The reverse is true of food, drink and tobacco, and textiles and clothing, which show little fluctuation in numbers, while with regard to transport and distribution, which exhibit movements independent of the trade cycle, it appears that insured workers flock into the distributive trades in times of industrial depression and abandon them in times of industrial prosperity.

The industrial structure of Merseyside is thus not wholly static, and Merseyside presents a different industrial structure from Great Britain as a whole both in nature of industry and in size of factory. In proportion to its total employment, Merseyside has a relatively large share of large factories. Analysis of the location of individual industries, which occupies the longest chapter of the report, leads to a discussion of the general factors affecting the location of industry on Merseyside, in which it is pointed out that industries which are highly localized on Merseyside almost all depend directly on imported materials, and the primary industries have a higher location factor than the secondary products derived from them. Moreover, Merseyside has few industries using primary materials produced within Britain, and where such materials are used it is in smaller quantities than imported materials. The pull of Merseyside on industrial location in respect of materials is chiefly bound up with the materials imported through the Port of Liverpool, those of low value in proportion to weight feeling the pull most strongly.

In respect of labour, the pull of Merseyside on industrial location affects chiefly those industries requiring labour in quantity irrespective of skill, and Mr. Smith notes that the requirements of skilled labour appears to be of decreasing importance in Great Britain as a determinant of industrial location, quantity rather than quality of labour being of significance. In regard to mobility and immobility, seed crushing, grain milling and sugar refining stand out clearly from the rest in every respect as essentially immobile. Cattle, dog and poultry foods, and to a lesser extent galvanized sheets, approach this group, while the most mobile of the industries considered are matches, telegraph and telephone apparatus, tobacco and aircraft. The major seat of industry within Merseyside is the dock and water-front zone, where all immobile industries are focused, as well as shipbuilding and repairing, constructional engineering and newsprint manufacture, all of which offer mainly male employment. In the extra-dock zone the industries show in the aggregate greater mobility and frequently provide more female than male employment.

In the third part of the report, discussing the future of population and industry in the area, the importance of such studies as providing the factual basis in reconstruction planning is well illustrated. The future magnitude of the population of Merseyside may be said to depend on the rate of natural increase—which on the whole was steady for the five years preceding the War, the extent of war casualties and of the maintenance of the armed forces after the War, the permanence of war-time evacuation and the extent of industrial migration. The future local distribution of population on Merseyside may be presumed to show a continuation or intensification of movements in progress immediately before the outbreak of the War. The future volume of industrial employment on Merseyside is likely to be profoundly affected by the trade of the Port. While the import of food through the Port of Liverpool is likely to be maintained and is unlikely to be greatly affected by changes in British agriculture, restrictions in the world's markets open to Britain are likely to have much more profound effects.

In commenting on possible dispersal of industry from the point of view of defence, Mr. Smith states that while a large agglomeration of factories is presumably an easier target for air attack than a wide scatter of factories over the countryside, the defence of a group of factories may be an easier problem than the defence of widely scattered units. Merseyside has claims to correct deficiencies in the provision of greater opportunities for skilled male employment and for a greater number of the new 'assembly' industries. For correct industrial balance, Merseyside needs more opportunities for skilled craftsmen, and there are many industries of this type possessing considerable mobility which might be directed to Merseyside if the central government contemplates control of industrial location. Such industries should be directed to the extra-dock zone, where the working conditions are better, where the product of a foodstuff can be made under more hygienic conditions and where labour lives within easier access of the factory. Moreover, as regards the industrial satellite in the Merseyside area, if it is not to drain life from its parent, its success appears to depend on the attraction of new industries from outside Merseyside altogether.'

There can be no two opinions as to the value of studies which bring out as clearly for other districts as this one does for Merseyside the factors which determine the volume of employment and local prosperity and well-being, and in their absence it can scarcely be maintained that local authorities are in possession of the knowledge which should be the foundation of their planning. Mr. Smith's report provides an admirable example of the way in which scientific method and investigation can contribute to the solution of major problems in a democratic society.

AUTOMATIC PRODUCTION OF OSCILLATOR SCALES

THE frequency of an oscillator is usually set by dial adjustments corresponding to a calibration chart from which the exact frequency corresponding to the dial indications may be obtained. The relationships between the frequency and dial markings, moreover, are different for every oscillator, so that a calibration chart must be prepared for each. This is not particularly difficult but is laborious, by reason of the need to refer for every reading to a calibration chart. It is much simpler to employ a dial marked directly in frequencies, but to provide such a scale by usual methods requires much time and labour when the frequency range is large and the accuracy is to be high. Although the scales for different oscillators are similar, they are not sufficiently alike to permit the scales for all oscillators to be printed from a single master film.

A method of printing such scales has, however, been recently developed and has been described by T. Slonczewski (*Bell Lab. Rec.*, 20, No. 11, July, 1942). A master scale A is used which, when placed over an unexposed film B, is moved with respect to B at a varying rate, such that at each 50-cycle point a line on scale A will be directly over its correct position on scale B. The section of film B is exposed at the instant it is under the corresponding line on film A. Two oscillators are used, set up facing each other, one serving as the standard and having an accurately marked film scale. The other, to be calibrated, carries on its sprocket the unexposed film that is to be marked, line by line, from the film of the standard, although the spacing of the lines will be different from the standard.

The condenser-driving spindle of each oscillator carries a worm-driven driving gear and film sprocket. For the duration of the calibration, 60-cycle synchronous motors are attached to the condenser worms of each oscillator. A standard motion-picture lamp is mounted behind the film of the standard, and a condensing lens focuses its rays in a narrow band over the section opposite the hair lines where the scale is read. The test oscillator motor receives its supply from the commercial 60-cycle supply. That on the standard is driven by a 'difference' frequency from the output of a modulator to which the output of the two oscillators is fed. When the two oscillators are 60 cycles apart, this latter motor will therefore have a 60-cycle supply, and the two films will be running at the same speed. As each line on the standard film passes through the band of light, it will be printed on the film of the test oscillator. The purpose of this drive arrangement is to vary the speed of the standard film in such a way that the line in the light beam corresponds to the frequency of the test oscillator except for the 60-cycle difference This 60-cycle constant difference is readily corrected after calibration by the low-frequency adjustmen that has been provided for this purpose.

EARTHED-PLATE AMPLIFIER FOR THE FREQUENCY-MODULATION TRANSMITTER

IN the United States, frequency-modulation ha been assigned the wave band 42–50 m.c and a these frequencies, simplification in design and reduction in size of transmitters are of particular importance because of lead reactances and stray capacitances to earth, which increase with frequenc and with size, and may become serious obstacles i large transmitters operating at high frequencies.

A 10-kw. transmitter has been developed recentl by the Bell Laboratories in which the difficultie have been overcome using the new Western Electri 389 *AA*, air-cooled valve, and by a novel circui arrangement due to W. H. Doherty. Even with thi new tube, however, it was found that there woul be sufficient stray plate-earth capacitance to resul in a rather large loss in the plate-tuning coil, and—of even greater importance—the tuning would b undesirably sharp.

Both these obstacles were overcome by the use an earthed-plate amplifier and a number of nov features described by A. A. Skene (*Bell Lab. Rec* 20, No. 11, July, 1942). The circuit employed resul in the stray plate capacitance-to-earth being i parallel with the plate-earthing condenser, which used to provide a radio-frequency path to eart while blocking the D.C., and thus has no effect o the operation of the plate circuit. Only the filamen to-earth capacitance remains and is very muc smaller than the plate-to-earth capacitance. Th filament is at a high radio-frequency potential, a it is very necessary to supply filament current witho operating the filament transformer at this hig potential above earth. It is also necessary to supp radio-frequency driving potential between the gr and filament from the driver unit, one side of whi is earthed.

An ingenious arrangement is described whi achieves these objectives. The normal plate-tuni coil is replaced in the new circuit by a coil betwe filament and earth, and is formed of a pair of copp tubes wound in parallel. The filament leads are threaded through the bore of one of the tubes and the grid-driving potential is supplied through an inner conductor of the other. At the filament end of the coil, each side of the filament is connected to the tubes via a condenser, the other end of the coil being earthed. Thus the filament current and grid-driving voltage are delivered at the required location with the driver and filament transformers maintained at earth potential. The article describes and illustrates the apparatus in some detail.

ISO-MAGNETIC CHARTS OF THE GLOBE

IN a series of articles which have appeared in issues of the quarterly journal *Terrestrial Magnetism and Atmospheric Electricity* (commencing with the issue dated December, 1940), Prof. Sydney Chapman gives the results of his valuable investigation of the general form which iso-magnetic curves should take on magnetic charts of the globe, and of the interrelation between the curves for certain components of the earth's magnetic field.

The magnetism of the globe assumed in the first-named investigation is that due to a 'dipole' centred upon an axis of the earth. Although this simplification only roughly corresponds to observed facts, and although in a generalized discussion local irregularities of the earth's field cannot, of course, be aken into account, some interesting and instructive geometrical features are shown to exist, knowledge of which can be applied with advantage in the construction of magnetic charts. Examples are: the hape of the curves near their nodes and singular points, the correspondence and relation of nodes and loci, and the course of the iso-lines near the magnetic or dip) poles.

In the second branch of his investigation, Prof. Chapman develops and demonstrates a method of esting the mutual consistency of data derived from so-magnetic charts of declination and horizontal intensity. Normally, the charts are produced independently. The line-integral of the magnetic force round a closed contour on the earth's surface can be used to calculate the intensity of current electricity passing between atmosphere and earth within the boundary. Direct measurement of air-earth current, however, shows that the current is actually much too small to be effective on the scale of the charts; and if significant values are obtained when the line-integral is taken, derived from chart readings of declination and horizontal intensity, round a vanishingly small area, the inference to be drawn is that errors exist in the data. These may originate in either of the charts or in both, and will probably be due to actual errors in the placing of the iso-lines y the chart constructor. In this case the position of such lines may be improved by trial even in the absence of fresh data; and since horizontal intensity in general less well determined than declination, substantial improvement in charts of horizontal intensity may be possible by this means.

Prof. Chapman has recently extended his investigation to isopors representing *secular change* in the values of the elements, a problem of considerably greater complexity. The results are published as otes VII and VIII of the series, in the issue of *errestrial Magnetism* of June, 1942.

Isoporic curves, more particularly over the oceans, are to a large extent inferential, since with the sources at present in existence for procuring observational data they are of necessity based on unevenly scattered and relatively scanty information, very largely obtained from fixed land observatories.

Secular change in the earth's magnetic field is itself subject to change which is sometimes quite rapid in limited areas. Consequently, a complete picture of the changes occurring over the whole globe at any one time must always be an ideal attainable only in retrospect.

The lack of mutual consistency detected by Prof. Chapman in areas on the charts he has examined emphasizes the need of additional observations of secular change in particular regions of the globe.

W. M. WITCHELL.

PUTREFACTION IN CATTLE HIDES

THE best method of drying hides is to lace them flat in a frame and dry them with access of air to both sides. Some delay between flaying and the suspension of the hide for drying is inevitable. Commercial practice has allowed this delay to extend to several hours, sometimes to 1–2 days. Experiments were therefore carried out at Kano in Nigeria and at Isiolo and Mombasa in Kenya ("Results of Delayed Drying Trials in Nigeria and Kenya", *Bull. Imperial Institute*, 40, No. 2; 1942). These three places represent a series of conditions of increasing atmospheric humidity and, to a less degree, increasing mean shade temperature, Kano having considerably the driest and slightly the coolest mean shade temperature and Mombasa the wettest and warmest.

In the experiment at Kano the hides were divided into two lots; one lot was given an arsenical dip immediately after flaying, the other lot was given an arsenical dip at the end of the delay period. Arsenical dips, if sufficiently strong, have some bactericidal effect. During the delay period the hides were folded hair out and left in the sun. Drying was in the sun. The dried hides were shipped to England and tanned for sole leather. The hides arsenicated before delay from the 8- and 16-hour periods showed no grain damage. Hides arsenicated before delay but left for longer periods and hides arsenicated after delay all showed slight grain damage in the finished leather. Except for this superficial damage the hides all proved to be sound. There was no damage due to Dermestes beetles.

In the experiments at Isiolo and Mombasa the experimental hides were divided in the line of the backbone, one side suspended for drying within two hours of flaying, the other folded and put in the sun for delay periods up to thirty-two hours. Drying was in the sun. In these hides there was a striking difference between the control and those with delayed drying. All the control half-hides were perfectly sound; the delay half-hides showed varying degrees of putrefaction, worse in the Mombasa hides than the Isiolo hides and increasing with the length of delay. All the control hides were free from damage by Dermestes beetles; the delay hides showed considerable damage both on the grain and in the carium, increasing with the degree of putrefaction. It should be noted that delay and control half-hides were shipped in the same bale. Although considerable putrefaction occurred in some cases it is interesting that the effect on the hide was strictly local. Sole leather from the damaged hides compared with sole leather from the control hides gives similar figures as regards resistance to abrasion, apparent density and water absorption. Nevertheless, it was proved that delay between flaying and drying causes considerable putrefactive damage, especially in a humid climate. D. JORDAN LLOYD.

FORESTRY IN ASSAM

ASSAM is still one of the most undeveloped provinces of India, in spite of the long period it has been under British Administration. This is in the main due to the considerable area occupied by the hill districts inhabited by various tribes whose chief method of livelihood is by the practice of shifting cultivation, that most wasteful of agricultural methods. The backward condition of these peoples must be attributed to the guiding rule of British administration that the customs of the people should not be interfered with, once tribal warfare and other practices incompatible with modern ideas had been stopped. The consequence is that, in spite of the lapse of well over half a century since forest conservation began to be introduced into parts of Assam, forest reservation has made little progress in the hill districts. Even in the Lushai Hills, we read in the "Report of Forest Administration in the Province of Assam for the year 1940–41", by C. Mackarness, Senior Conservator of Forests (Shillong, Assam Govt. Press, 1941) "A Forest Regulation has been proposed and a draft submitted to Government which in a modified form has been forwarded to the Governor-General in Council for assent." The report on this subject continues: "The hill districts of Assam possess an inadequate proportion of Reserved or Protected forests which provides one reason for erosion and flood damage." It may be asked, it is being asked with increasing pertinence, when will the Governments of the British Commonwealth of Nations—for the matter is equally urgent in many of them—face up to this question of the enormous damage and waste which is increasing annually through deforestation erosion and flood damage. It may be that the War may prove the salvation of these Assam hill districts, since it would seem apparent that for military purposes communications are being opened up in what has heretofore been a wild mass of more or less inaccessible hill tracts.

Another factor on which evidence is forthcoming in this report is the want of collaboration between the Agricultural and Forestry Departments, no new thing unfortunately in the Empire, as recent reports have shown here in Great Britain. In spite of the vigorous opposition of the Assam Department a part of the Jamira forest has been disforested for permanent cultivation. It has since been found that this is impossible owing to the hilly configuration, as has been pointed out by the forest officers and since confirmed by the settlement operations. To the Forest Department will fall the task of endeavouring to reafforest the area. The Government policy vis-à-vis the large area of so-called Unclassed Forests in which no reservations have been made appears to be dangerously vacillating, in spite of the fact that a considerable proportion of the forest revenue comes from these large tracts amounting to some 16,000 sq. miles, and that protection for some of the area must be of vital importance to the country as a whole.

An item in the report of interest to those who have studied the question of the preservation of the fauna of India and elsewhere is the reservation of a considerable tract of forest as a sanctuary for wild buffalo in North Lakhimpur. Assam was an early leader in India in the formation of such sanctuaries, the first being for rhinoceros.

The report merits careful study; it includes special notes on the work of the departmental research officers. It is also a model which might be followed, for it includes a number of excellent photographs depicting various forestry operations and also three pictures taken by honorary forest officers in game sanctuaries of wild buffalo, sambhar and—a striking portrait—of a tiger advancing in the jungle towards the spectator.

FORTHCOMING EVENTS

(*Meeting marked with an asterisk is open to the public*)

Monday, October 12

INSTITUTE OF PHYSICS (at the Royal Institution, 21 Albemarl Street, London, W.1), at 10.30 a.m.—Discussion on "The Educatio of a Physicist"; at 2 p.m.—Discussion on "Training for Researc in Industrial and Applied Physics".

SOCIETY OF CHEMICAL INDUSTRY (YORKSHIRE SECTION) (under th auspices of the Chemical Society, Leeds Area Local Section, in th Chemistry Lecture Theatre, The University, Leeds), at 6.30 p.m.— Dr. F. Fairbrother: "Radioactive Isotopic Indicators".

Tuesday, October 13

CHEMICAL ENGINEERING GROUP OF THE SOCIETY OF CHEMICA INDUSTRY (joint meeting with the INSTITUTION OF CHEMICAL ENGINEERS) (at the Geological Society, Burlington House, Piccadilly, Londo W.1), at 2.30 p.m.—Mr. E. F. MacTaggart: "The Production Radium".

INSTITUTE OF FUEL (at the Institution of Electrical Engineer Savoy Place, Victoria Embankment, London, W.C.2), at 2.30 p.m.— Mr. W. M. Selvey: Presidential Address. Dr. Arno Carl Fieldner "The Analysis and Testing of Coal in relation to its Properties an Utilization" (Melchett Lecture).

ILLUMINATING ENGINEERING SOCIETY (at the E.L.M.A. Lightin Service Bureau, 2 Savoy Hill, London, W.C.2), at 5 p.m.—Mr. R. Ackerley: "Seeing is Believing" (Presidential address).

Wednesday, October 14

SOCIETY OF CHEMICAL INDUSTRY (FOOD GROUP) (at the Chemic Society, Burlington House, Piccadilly, London, W.1), at 2.15 p.m.— Dr. Magnus Pyke: "Vitamin Content of Certain Vegetables"; M A. J. Curtin Crosbie: "New Beer Disease Organisms"; Mr. Alan Ward: "Location of Vitamin-B_1 in Wheat".

Friday, October 16

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDE (at the Literary and Philosophical Society, Newcastle-upon-Tyne), 6 p.m.—Annual General Meeting. Mr. J. Ramsay Gebbie: Presidenti Address.

Saturday, October 17

NUTRITION SOCIETY (at the London School of Hygiene and Tropic Medicine, Keppel Street, London, W.C.1), at 11 a.m. and 2.15 p.m.— Conference on "Trace Elements in relation to Health".

Sunday, October 18

ASSOCIATION OF SCIENTIFIC WORKERS (SOUTH WALES AREA) (the Royal Hotel, Cardiff), at 10 a.m.—Conference on "Science Victory".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on before the dates mentioned:

LECTURER IN MECHANICAL OR ELECTRICAL ENGINEERING in t Cannock Chase Mining College—The Director (H), County Educati Offices, Stafford (October 14).

GAS ENGINEER and MANAGER of the County Borough of Warringt Gas Undertaking—The Town Clerk, Town Hall, Warrington (endors 'Engineer and Manager') (October 16).

ASSISTANT AGRICULTURAL ORGANIZER to the Holland County Coun Agricultural Education Committee—The Principal, Agricultu Institute, Kirton, Boston, Lincs. (October 17).

TEACHER FOR DAY AND EVENING ENGINEERING CLASSES—T Principal, County Technical College, Gainsborough, Lincs.

WOMAN LECTURER IN PHYSIOLOGY—The Principal, Liverp Physical Training College, Barkhill Road, Liverpool 17.

LECTURER IN ENGINEERING at the Achimota College, Gold Coast The Secretary, Overseas Manpower Committee (Ref. 391), Ministry Labour and National Service, Hanway House, Red Lion Squa London, W.C.1.

THE ENGLISH COUNTRYSIDE

THE report of the Scott Committee on Land Utilisation in Rural Areas completes the work begun by the Royal Commission on the Distribution of the Industrial Population, the terms of reference of which excluded the consideration of agriculture ; and although its major and minor recommendations are sometimes rather confusingly blended, the report is clearly a reconstruction paper of the first importance. It has life and colour and gives substance to some of those aspirations for an ampler and more satisfying national life which the War has accentuated. Moreover, like the interim report of the Uthwatt Committee, it reiterates the importance of immediate action. A survey of the report appears on p. 448.

Broadly speaking, the Scott report, like that of the Barlow Commission, centres upon two main recommendations : first, that there should be national long-term planning for industry and for agriculture in England and Wales ; and secondly, that for that purpose a national planning authority should be set up. Both principles have been restated by the Uthwatt Committee in its report, and the Government has repeatedly announced its adherence to these views and declared its intention to establish the requisite planning authority. The Scott report should dispose of whatever hesitation has been responsible for the protracted delay in bringing intention to performance. The final argument is convincing : "It is our firm belief that a vital incentive to the war effort is the presentation of a clear picture of a better world which lies ahead and which, if plans are drawn up and the essential preparations made in advance, can be achieved after this struggle is over. To delay planning and the legislation to carry the plans into effect until the time for action is upon us—the end of the war—we believe to be a fatal error."

That is the fundamental conviction behind all the pressure for planning for reconstruction both nationally and internationally, and the case for immediate planning could scarcely have been put better than by the Scott Committee.

This conclusion is reinforced by the melancholy record of the effects of the Town and Country Planning Act, 1932, and the Restriction of Ribbon Development Act, 1935, reviewed in the sixth chapter of the report, which deals with planning powers. This is a striking illustration of the futility of any piecemeal attack on the problem. Despite its complexity it must be tackled as a whole, though strangely enough, there are matters in which the majority report consistently fails to do so—notably in regard to agriculture.

The poor equipment which Great Britain possesses at the moment for dealing with the most pressing tasks in this field gives special interest and importance to the recommendations of the report in regard to machinery. Here the Committee, assuming that the policy of the Government involves the establishment of a Central Planning Authority, proposes that machinery should be set up now to make plans for the use of land, and that the necessary legislation should be passed so that the plans can be put into operation immediately on the cessation of hostilities. The report outlines a definite scheme of work to be accomplished in five years, and it distinguishes carefully between planning and development—between the formulation of a national plan and its execution.

Planning, the Committee considers, should be the function of the planning body within the Government, and development the concern of the separate Ministries. Moreover, despite insistence on a Central Planning Authority, the Committee does not regard its recommendations as involving any specific form of Government machinery. In fact, it considers that the establishment of a separate Ministry of Planning is undesirable and that it is impossible to visualize a Central Planning Authority taking over the execution of planning proposals or any other form of development in those spheres which are the direct concern of existing Ministries. The proposals involve a transfer from the Ministry of Works and Planning, as constituted under the recent Act, of all planning functions, in order to separate them from the development functions of that Ministry.

As to the machinery, the Committee appears to be unanimous. When we come to the general character of our future policy and the aims that should guide our plans, there are serious differences of opinion between the majority report and the minority report signed by Prof. S. R. Dennison. On many questions there is indeed agreement, for example, in regard to the restoration of the village crafts and the improvement of rural life, but Prof. Dennison in his minority report puts forward an entirely different outlook and perspective, and his criticism is both trenchant and fundamental. The question he raises as to the relative efficiency in use of our resources is the one which gives the report a major claim on the attention of scientific workers.

In their introduction the majority, while endeavouring to evaluate and assess the significance of the permanent physical factors in the shaping of the countryside, have sought to avoid the temptation of looking back to the past and seeking to perpetuate it, and in their recommendations they clearly seek to look forward and to visualize many changes. They recognize that British agriculture, however vital to the nation in time of war, cannot be maintained in the same position in time of peace. The conditions to be imposed on constructional development in the countryside must be such as will be consistent with the maintenance of a prosperous and progressive agriculture. The Committee is mindful, too, that the pre-war prevalence of malnutritional disease must never again be allowed to recur.

The gravamen of Prof. Dennison's criticism is that, while facing change, the majority are afraid of it; they are excessively tender to the general body of agricultural interests, allowing it too large a say in matters which concern the nation as a whole. He disputes entirely, for example, the whole idea on which is based the recommendation of the majority that land which is included in one of the categories of good land should not be alienated from its present use unless it can be clearly shown that, on balance, it is in the national interest that the change should be made; he would throw the onus of proof not on the applicant who seeks to make the change, but on the agricultural occupier or interest, who should be required to show cause why land should not be diverted to some other use. In this way, he argues that, using the machinery of planning control, while the best land would not be unnecessarily alienated from agriculture, constitutional development would not be hindered by the maintenance of land for agriculture unless a clear case of national advantage were established.

Prof. Dennison maintains that the majority are inclined to treat village life and agriculture too much as if they were museum pieces and to preserve them by methods which threaten the standard of life both of the villages and of the nation. Fear of the disturbing effects of the introduction of industries to the countryside leads his colleagues, in his view, to overlook the advantages they would bestow. Moreover while evidence was submitted that changes in agriculture may well result owing to national nutritiona needs, the bare fact is noted in the majority report and it is left to Prof. Dennison to elaborate the point His observations on the probable effect of the new ideas of nutrition and protective foods on agriculture is only one example of the way in which his minority report gives precision and incisiveness to a documen which, despite many admirable features, is somewha discursive and vague, and lacks the lucidity of th Barlow Commission's report.

The difficulty—and the differences between the majority and the minority reports—arises in the interpretation of what is meant by "the maintenance of a prosperous agriculture", "the well-being of rural communities" and "the preservation of rural amenities". In regard to the first, Prof. Dennison bases his argument on economic considerations an the relation of the maintenance of agriculture to th standard of life of the rural worker. Both the exten and the type of agriculture are involved, and althoug recent reports from the industrial side dealing wit reconstruction recognize the importance of a correc balance between industry and agriculture, th majority report carries the analysis little furthe Prof. Dennison considers that the assumptions the majority report would only provide bett standards of life for the rural worker at the expens of the community.

In a progressive society, the ultimate prosperit of agriculture must depend upon increased efficiency but this is not necessarily achieved by increase output. Greater specialization may also be importan particularly in regard to improved nutrition. Th depends upon the type of food as well as on quantit involving more vegetables, milk and other protecti foods which traditional agriculture in England ar Wales has never supplied in adequate amounts; an as Prof. Dennison rightly points out, the needs of th consumer as well as the quality of the land mu determine what shall be grown. The aims of ag cultural policy in Great Britain should be, as Viscou

Astor and Mr. Rowntree put it, "to promote a happy marriage between nutrition and agriculture rather than to shut out overseas competition, to improve the conditions of the agricultural labourers rather than to increase their numbers, to treat agriculture as an industry or group of industries . . . existing for the purpose of satisfying human wants with the minimum of toil, rather than as a way of life to be preserved with the minimum of change".

The essential point in determining the type and size of agriculture is that the full measure of economic progress, the improvement of standards of living, can take place only if, as technique and economic conditions change, resources are no longer deliberately impeded in their movement from uses which yield a small return of goods to those which yield a larger return. To attempt to retain resources in any existing form of activity which gives a lower product than others, which are new and developing, must involve a loss to the community in general, in that standards of life as a whole are kept down. What has to be remembered is that, as Prof. Dennison again points out, for many types of produce we can obtain more food by employing labour and capital in manufacturing goods which are exported, and importing food in return, than we can by using the same amount of labour and real capital in agriculture to produce the food directly. This is one of the recognized advantages that Great Britain has over Germany, and the answer to the argument that a large agriculture must be maintained for purposes of security in time of war. The need is not denied, but it will not be achieved by methods which are wasteful of man-power in war as well as in peace. Malnutrition will not be conquered by growing more food at great cost, but by cheap food, obtained with the minimum expenditure of resources.

Social policy might well be directed to increasing the demand for the protective foods—for example, milk—so as to cushion any fall in the agricultural output in other directions, and this is a legitimate contribution to the well-being of rural communities which is not at the expense of the whole community. Prof. Dennison, however, differs from the majority of his colleagues in holding that the rural community, if it has lower standards as a result of lower wages in agriculture, should not be protected from the impact of higher standards. While supporting such recommendations for the improvement of rural life as spreading village colleges like those now established in Cambridgeshire, village halls, village playing-fields, and the universal supply of electricity, he holds that the introduction of a certain degree of industrial development offers the best hope of improving the social and economic conditions in the countryside. The two main advantages are the provision of alternative employment, usually with higher standards of living, and the introduction of improved physical and social services.

In regard to the preservation of amenities, Prof. Dennison challenges the majority view that amenities depend on farming, or even on a particular type of agriculture. Changes in the type of farming and the development of physical reconstruction may bring changes in the countryside, but there is no reason why they should not create greater amenity than existed before. It is in fact difficult to conceive of a more fitting way to use land in the national interest than to use it for the new construction necessary to provide better living conditions for the people—and their children after them—now dwelling in congested towns. In particular, it is important not to attempt to preserve amenities which can only be preserved as long as full access to them is denied to those whose heritage they are.

Socially and politically, it is clearly undesirable to foster a cleavage of interest between agriculture and the rest of the community by isolating the countryside from the effects of the impact of town life. Agriculture and agricultural workers have a more positive part to play in the life of Great Britain, and they can only play it if they are brought more closely into touch with what is the major part of British life. Equally it is true that closer contact with the countryside is desirable to give balance and health to the industrial population, and an agricultural policy which accepts as inevitable an antagonism between town and country would be nothing less than a national disaster.

The happy marriage thus foreshadowed between agriculture and nutrition could have no more valuable consequence than that the changes in agriculture would involve a smaller number of workers in a prosperous agriculture providing adequate standards for the worker and making isolation as unnecessary as it is undesirable; such changes, if combined with careful control of constructional developments, would leave unimpaired the major amenities of the countryside, and also create new forms of amenity, all of which would be accessible to a larger proportion of the population than can enjoy the countryside to-day. Such a policy would firmly establish a harmony of interest between town and country which would make for mutual understanding, goodwill and the dynamic adaptation which Prof. Dennison is assuredly right in holding should mark a positive policy in the interest of the nation as a whole.

Whatever the difference between majority and minority reports in regard to outlook and policy, and as to the objective which should guide a national policy—and clearly these are great—there is agreement as to the imperative necessity for more effective planning of land utilization in England and Wales. Both apply pressure at the point at which the Government is most dilatory, and there will be grave dissatisfaction if there is now any further prolonged delay in providing the machinery and the legislation in readiness for the work to be done when the War is won. A large part of the means of establishing a policy which will command the full support of forward-looking minds in all parties is now in the hands of the Government, and though it is clear that there are fields in which policy has yet to be thought out and investigations completed, public opinion will assuredly look for the action which will equip the country to seize the opportunities which will presently be ours.

THE TRIUMPH OF TIME

The Conquest of Time
By H. G. Wells. (The Thinker's Library, No. 92.) Pp. x+86. (London: Watts and Co., Ltd., 1942.) 2*s*. net.

THIS little book has been written by Mr. Wells to supersede "First and Last Things", which was his attempt in 1908 "to get my ideas about the world and myself into some sort of order". The new volume is stated on the cover to be the author's presentation of "the final fruits of his philosophic thought", and he himself presents it as "a fairly lucid and consistent summary of modern ideas concerning the fundamentals and ultimates of existence". The change of title is at least appropriate, for one who has conquered time becomes as God, with whom there is no last or first, and the brevity of the book is as commendable as it is rare in a treatment of so large a theme.

Mr. Wells's philosophy is as follows. The individual human life is a synthesis of isolated experiences, often mistakenly regarded as continuous. This illusion of temporal continuity creates a dread of its cessation, death, and of pain, and gives rise to an idea of persistence after death which imposes the tyranny of the dead past on the living present. The individual is actually an element in a larger structure, the species, with which it interacts. The character of the species largely determines (through both physical inheritance and mental adaptation) the character of the individual, whose variations from the norm in turn react on and modify the character of the species. The individual life is thus not "a tale told by an idiot"; it is a factor in the progress towards "the awakening of consciousness in the universe". As the universe through the species advances to this goal, the successive generations of individuals gradually become freed from the tyranny of time. They cease to fear death, they acquire more knowledge of the forgotten past and more insight into the future, thus acquiring "an ever-expanding Now". The religion of the new man "demands the subordination of the self, of the aggressive personality, to the common creative task, which is the conquest and animation of the universe by life". The full course of the individual human life will be "from action to an ultimate serene and impersonal contemplation. The body and the personality will die at length like an old garment laid aside".

All this drama of evolution, however, is simply an appearance to our conscious life of what is actually a rigid, determined system in four-dimensional space-time. The latter is the reality; "it is simply from the subjective and illusory point of view that there seems to be free movement"—that is, movement along the time axis. "Our consciousness is a series of delusively unified conditioned reflexes"—an "illusion of a unified personality" which "joins up a series of traces which constitute our conscious life". The passage of time is an illusion; all that is actual in personal life is a discrete set of static points in the rigid four-dimensional system, and somewhere in that frame, at places having higher values of the *t*-coordinate than ours, a very much larger number of points—"the universe"—possesses consciousness (which presumably means that it also has illusions, though Mr. Wells does not state specifically what the life of the universe is). This is the conquest of time.

As a summary of a lifetime's study of the fundamentals and ultimates of existence, the book is surprising in two respects. In the first place, it is written more carelessly than one would have thought fitting for the occasion. True, we sometimes meet the perfect phrase—for example, the reference to "a God-shaped void" in the mind of the infant—but more often passages occur which seem meaningless, such as "this present period of world warfare, in which . . . people die far more significantly than they have ever died before", or "Natural Philosophy . . . went along the line of science, in the expectation that a great free correlation of individual effort would ensue without further effort as the collective truth". Secondly, there is little of the "serene and impersonal contemplation" which is to mark the maturity of the new man and which, we are told, one may "share to a very considerable extent even now". The book is as full of vigour and combativeness as anything that Mr. Wells has written; it looks for strength in vitriolic protestation rather than in quietness and in confidence. It impresses one, in fact, as the product more of temporary excitement than of settled conviction.

It is, however, the substance of the book, and not its form, that calls for chief attention, and it may be said at once that it is unconvincing. To explain why, it is necessary to consider briefly what we mean by time, and how we have come to mean it.

It is not generally realized by modern scientific thinkers what little prominence time had in pre-Galilean philosophies. It was taken for granted as being practically identical with consciousness itself, thus calling for no special thought on its own account. The great achievement of Galileo was to create conceptions in terms of which motion could be treated mathematically, and to this end he represented time as *a space-like dimension which could be measured*—divided up into equal parts as a length is. But this dimension, or spacified extension, of time was so conceived for the one purpose of making motion amenable to mathematical treatment. The world describable in terms of it was specifically limited by Galileo to the world of mechanical phenomena. All else—even physical experiences like heat, sounds, smells, colours and the rest—he excluded from this world and located in the perceiving being.

It is difficult to over-estimate the value of this colossal achievement, for it has made possible the whole of modern physical science. It is difficult also to over-estimate the illusions it has created, for, having seen the value of the concept of 'spacified' time in mechanics, subsequent thinkers, less perspicacious than Galileo, have taken it to be a universal receptacle for the whole of human experience, and therefore as representing in a more precise form everything that human consciousness has ever meant by time. Consequently, the whole of experience has been distorted to fit a concept to which most of it is non-conformable. Our experiences have been ranged out in the mathematical continuum, and hopes and fears and passions (which are obviously non-spatial) have been placed cheek by jowl with the spatial positions of mass particles as occurring at such and such instants of spacified time, and the incongruous "history" thus built up has been regarded as something objectively "true" and infinitely more "realistic" than the direct experiences which have been so regimented.

How different our modern conception of time is from that of pre-Galilean thinkers may be illustrated in several ways, of which perhaps the simplest is to ask what we mean by the "reversal" of time. We take this now to mean simply a reversal of the order of events in the time sequence, made visible by running a cinema film backwards, because we have lost the habit of thinking of time except as a space-like dimension. To a pre-Galilean, however, the phrase would have seemed rather silly, but it would have suggested a state of mind in which one knew the future but not the past, and as fast as the future became realized it would be forgotten except in so far as we might calculate it as we now calculate future eclipses. The reversal of time would have been a passage from actuality into impotentiality, instead of that from potentiality into actuality of which we are, in fact, conscious. The loss of ready awareness of this aspect of time, and the imposition of another, admirably suited for its purpose, on the whole of experience, for most of which it is not at all suited, is the true tyranny, and the first step towards any conquest of time must be the relief of our thought from this incubus.

Towards this end Mr. Wells contributes nothing. He accepts unquestioned the Galilean conception, in its Einstein-Minkowski rather than its Newtonian development, and is blind to all that it ignores. He tries to mould experience to fit it, and thinks that he has thereby released experience from it. His "conquest" of time is, in fact, a complete and whole-hearted surrender. He maps out the history of the individual and the species; shows where our various emotions and aspirations are located in the time sequence of the individual; is convinced that when he has so distributed all the experiences which come within range of his knowledge the individual ceases to be; and sums up our personalities as merely "serviceable synthetic illusions of continuity".

Mr. Wells's view of the space-time continuum of relativity is fundamentally erroneous. That continuum is a conception, a development of the original Galilean terms more flexible than the Newtonian development, and so better fitted for the purposes of mechanical physics. It is not, as Mr. Wells imagines, something independently existing to which experience must be adapted, but precisely the reverse. We do not explore the universe and count its dimensions; we try to rationalize our experience of movements, and choose as a means of doing so the concept of a continuum of 1,2,3 . . . . or n dimensions, whichever makes our task simplest. In science experience is sacred. We may describe it as we like in order to establish rational relations between one experience and another, but what we cannot do is to deny it; hence whatever we do with motion cannot legitimately contain a denial of it. Now let us hear Mr. Wells: "From the standpoint of the space-time continuum there is no movement; the whole system is rigid. It is simply from the subjective and illusory point of view that there seems to be free movement." He takes the Frankenstein monster and puts the experience for which it was created under its control.

This inversion of the order of scientific reasoning, by which experience is subjected to the creations of reason instead of being the origin and end of their creation, is so vital to the whole subject that another example will not be out of place. "In our universe", writes Mr. Wells, "the extreme limit of motion is 299,796 kilometres a second. Nothing has even been known to go faster than that. You can imagine yourself doing so, you can imagine yourself on a rocket going at 299,796 kilometres a second, and you can imagine yourself standing up and leaping forward so as to go faster than that alleged maximum. But in reality you cannot do that. You are imagining the impossible."

This is quite wrong. Whether the rocket is moving with any speed at all or is at rest, you can leap forward just the same; it is, in fact, the first principle of relativity that what happens in a system is independent of the uniform motion of that system as a whole. The finite maximum of material velocities is a characteristic not of motion but of *the terms in which we choose to measure motion*. What is true is that, when we leap forward from the rocket, an observer to whom the rocket is moving at Mr. Wells's speed and who adopts our customary method of measuring velocities, will find our speed represented by the same number as that of the rocket. But we can with equal justification choose a different scale of velocity units such that any velocity up to infinity is possible. Bridgman has described a simple process which will serve our purpose. Imagine a framework carrying a string along which a transverse vibration may be sent at a definite speed relatively to the framework. Call this unit speed. Now let the framework of an exactly similar system travel side by side with this vibration. The vibration of *its* string will then move forward (relatively to the first framework, which is the standard of rest throughout) at two of our units of speed. By continuing the process we can build up a scale of velocities extending upwards to infinity.

Now let us measure some naturally occurring speed—that of an α-particle, say—by such a scale. Then there is no limit to the speed which may be reached. We may imagine a particle, when it is near the speed of light, emitting an electron in the same direction which travels twice as fast by this scale as the particle itself. By our ordinary system of measurement the electron would be reckoned as moving only slightly faster than the α-particle. That is because the limitation is inherent in the method of measurement; it is not something imposed on the behaviour of the moving body.

We may take a third system of measurement. A moving body can exhibit a Doppler effect, and we can measure its speed by the displacement of a spectrum line. Choose a scale of velocities such that velocity is proportional to the change of wave-length, $d\lambda$; for any speed small compared with that of light this will be very close to our present scale. But now with this scale a speed of recession may be infinite, but a speed of approach cannot be greater than a certain finite value, simply because a wave-length can be *increased* without limit, but cannot be *decreased* below zero. The same moving body, measured from in front, moves with the finite speed of light, and, measured from behind, moves infinitely fast. The fact is that we can impose a finite limit on speeds, or let them become infinite, by suitably choosing our arbitrary procedure for measuring them. This is literally true, because "finite" and "infinite" pertain to *measures*, and not to what is measured. They are characteristics of *numbers*; they have nothing to do with experiences—or with Nature, if one prefers that term.

The deeper insight into the character of scientific reasoning which relativity has made possible is not to be fully appreciated in a generation, and no reasonable person would expect Mr. Wells, whose synoptic view takes the whole field of human endeavour as its field, to be familiar with all that many specialists still find strange and paradoxical. But when he takes this very point of the maximum attainable velocity as the text for a sermon on the "great irritation of commonplace people" faced with the necessity of shedding cherished ideas; and, further, builds on his own misconceptions a system of philosophy which he presents with such blind dogmatism that he can declare that one who sees its worth "is bound to regard a bishop or a contemporary statesman as somewhat of a barbarian and morally and mentally his inferior. . . . It is difficult to talk to them as equals"—even those who most admire Mr. Wells's great gifts and are most conscious of the sincerity and disinterestedness of his efforts towards a better and happier state of existence, must feel the necessity of pointing out that his magnificent castle is nothing but a mirage, and that he has little chance of seeing anything more substantial until he is prepared to grant some measure of intelligence to those who announce a different prospect, even though to him it may seem only a sandy waste.

So much for the error which lies at the root of Mr. Wells's philosophy. It remains to indicate the illusory character of the most prominent feature of the philosophy itself. He is clearly justified in regarding the individual, the self, as a conception ("illusion" is not the right word) of continuity binding together a discontinuous set of memories. I can remember some incidents in my life, between which gaps exist in the time-scale, and to rationalize my experience I therefore form a conception of a continuously existing individual, my "self", of whose career I have forgotten some portions. In the same way, if I observe a sunspot on Monday, miss the cloudy Tuesday, see it nearer the centre of the sun's disk on Wednesday and later near one limb of the sun, lose it for a fortnight or so, and then pick it up near the opposite limb, I form a conception of a continuously existing spot which has rotated uninterruptedly with the sun. There comes a time, however, when I no longer see it where the postulated continuity of existence would lead me to expect, and I say that it has ceased to be —or has "died" if I wish to be poetic. Now it may be that my continuous self will similarly cease to be—I do not doubt it—but I see no reason to suppose that therefore I, who conceived it, will thereupon cease to be conscious, any more than I ceased to be conscious when the sunspot ceased to be. Anyone who thinks I will must give some reason for his belief; there is none in the mere ending of what Mr. Wells goes so far as to call an "illusion".

The fallacy in Mr. Wells's argument is that he confuses the subjective, conscious individual, which is never in the time dimension or time stream or whatever it may be called, with the postulated object of consciousness—the continuously existing self which is conceived so that it does lie along the time axis. The one fundamental and inescapable characteristic of the conscious individual is that it is always and only at the present; I cannot be conscious at any time but *now*, and this is not an accident, it is obviously of the very essence of consciousness. The conquest of time consists simply in realizing that we already know that. All the interactions of the postulated individual and the postulated species which Mr. Wells describes so succinctly are actual and important, but they do not touch the question of the destiny of the conscious individual; they refer to a few among the many things of which he is conscious.

Despite the length of Mr. Wells's extension along the t-axis, he is still mentally as young as ever. We may therefore hope that in after-years, when these wild ecstasies shall be matured into a sober pleasure, and he has reached the serenity of contemplation into which the individual life shall widen out, he will give us another version of the final fruits of his philosophic thought. It is distressing to think that a life of such great achievement and penetrating vision should culminate in such an anticlimax.

HERBERT DINGLE.

INTROSPECTIVE PSYCHOLOGY

Body and Self, One and Inseparable

Also Cosmic Rays and Light and other Writings. By Percy A. Campbell. Pp. vii+156. (San Francisco: George Fields, 1942.) 2.50 dollars.

THIS book consists of an essay in introspective psychology, and miscellaneous papers written between 1933 and 1942, which are chiefly concerned with the primary cosmic rays.

The value of any work in introspective psychology is difficult to assess as there is no objective standard against which it can be measured. It can only be referred to the self-observation of the reader, who, if he is to avoid dogmatism, must tacitly prefix the phrase 'so far as my experience of myself is concerned' to any judgment which he may make about it. The only approach to an objective standard would lie in the work of great artists, poets and philosophers, whose peculiar genius it is to express emotional and intellectual experience which is common to all, and in which we realize ourselves to be at one. The language of this experience being artistic and conceptual symbolism (as found in great works of art and systems of philosophy), introspective psychology would appear to be an inhabitant of the mind's no-man's-land, belonging neither to science, art, nor philosophy. In my own view, however (and all statements in this review will perforce be based upon that), the value of such an essay as this lies in the fact that it does strike a note in the mind of the reader which sets him thinking; and that it does suggest a new pattern for his thought useful to him in whatever branch of life he may be working.

Mr. Campbell was a pupil of William James for a short time, and the essay takes the form of a commentary on James's thought and psychological observation. The main thesis is that the centre of consciousness is not in the brain, but in the sensorium. The brain is merely the 'central telephone exchange'. Consciousness proceeds from the functioning together of the various elements in the body. The James-Lange theory, referred to frequently in the essay, is the classic example of this position. It follows that 'conscious is as conscious does', and that psychology has no need of a separate self, a *deus ex machina* aloof and exalted. Individuality depends upon the manner of integration of the bodily functions. To take an analogy from art, the self is like an æsthetic whole, which is dependent for its own particular wholeness upon the relationship of the elements used in its creation: though these elements—for example, colour, form, and canvas—may not vary, they may produce an infinite number of 'wholes'.

Another implication of Mr. Campbell's position is "consciousness is consciousness only to itself". Belief in the soul is a "song of the sensorium"; a false sense of selfhood and separateness arising from the play of consciousness upon itself. Many great thinkers have been "soul-mongers", and Mr. Campbell instances James himself as an outstanding example.

Mr. Campbell's thesis strikes a very familiar note in my sensorium (or, rather, in the sensorium that is me). The intellectualist *deus ex machina* is well and truly consigned to limbo, together with all the notions of separateness which go with it, and all the volumes of metaphysical sticking-plaster which have gone to rectify a state of affairs which never existed. Sentimental 'uplift' has been well and truly pinned down as a "song of the sensorium", and one finds oneself collecting other examples of that handy form of entertainment. But does Mr. Campbell go far enough ? After reading his book I find Shelley's question rising unbidden in my mind :

> "Whence are we, and why are we ? Of what scene
> The actors or spectators ?"

To pursue the analogy of the self and the artist's canvas, what of the *idea*, the motive force which both preceded the grouping of colours and forms and which finds expression as the genius, the *raison d'être*, of the picture ? It did not just happen. It was generated in someone's mind. Does Mr. Campbell, therefore, pursue his analysis far enough to be justified in his conclusions ? If the affirmation of the soul is a 'song of the sensorium', the negation of the soul smacks dangerously of being another. Although it is agreed that there is no separate self, the existence of a principle of integration, different in different individuals, is actually implied by this essay, while involving no idea of separateness. Some such notion as this seems to have been at the back of James's mind in the passage quoted as an example of his "soul-mongering".

"The perfect object of belief would be a God or 'Soul of the World' . . . so definitely conceived as to show us why our phenomenal experiences should be sent to us by Him in just the very way in which they come. . . ." ("Principles of Psychology", vol. 2, p. 317, quoted on p. 116).

Lastly, it is worthy of mention that the greatest 'soul-mongers' have been fully convinced of their own impermanence, and have been certain that their reality lay in their being an effluence, an expression, a creation. B. M. B.

DISCUSSIONS ON CITIZENSHIP

Handbooks for Discussion Groups

No. 1 : How to Lead Discussion Groups. By E. M. Hubback. No. 2 : The Democratic Idea. By Francis Williams. No. 3 : Is Britain a Democracy ? By Frank Hardie. No. 4 : Our Towns. By Elizabeth E. Halton. Pp. 24 each. (Published for the Association for Education in Citizenship.) (Bickley : English Universities Press, Ltd., 1942.) 3*d.* net each.

THE series of Handbooks for Discussion Groups which has been issued by the Association for Education in Citizenship, judging by the four which are here under notice, appears to be admirably designed for the purpose it seeks to serve. There can be no two opinions in a democratic society as to the crucial importance of the organized discussion of the social, economic and political problems which have arisen or are arising out of the War. The pamphlets are based frankly on the idea of democracy and in support of what the enemies of the democracies in this War are attacking under the name of humanitarianism. Moreover, this conception of fundamental human rights as individuals and as citizens is recognized as carrying the corresponding obligation for the community as a whole of securing for its members the fullest development of which they are capable in both these capacities, and at the same time of training them in respect for the equal rights and freedom of others.

The first of these pamphlets, by E. M. Hubback, "How to Lead Discussion Groups", deals with the efficient setting up and running of such groups. It is intended mainly for the use of less experienced leaders and chairmen of small groups anxious to discuss public affairs, but the greater part of the pamphlet is occupied by an excellent bibliography ranging over modern political ideas ; government institutions and social and economic problems in Great Britain ; the British Commonwealth ; foreign countries ; international affairs ; and on clear thinking and psychology. This bibliography, though selective, is well balanced and should render the pamphlet of much wider service than to the novitiate in group discussion.

Mr. Francis Williams's pamphlet (No. 2. "The Democratic Idea") is of an entirely different type. In four brief chapters he sets forth lucidly and suggestively the challenge that is inherent in the democratic idea, its slow emergence from the first stirrings in ancient Greece to the American Declaration of Independence, its meaning and effect on the whole pattern of our lives, the values that spring from this recognition of human dignity, and the practical problems that confront us as we seek to translate the ideals of democracy into a system of living as a community. The task of relating the latest expression of democracy in the four freedoms of President Roosevelt with its historical origins and slow evolution could scarcely have been better done in such brief compass, and Mr. Williams does not fail to lay stress on the duties as well as the privileges of democracy, or to indicate the ways in which we may equip ourselves to discharge such responsibilities.

Elizabeth E. Halton's pamphlet (No. 4. "Our Towns") is equally felicitous. Her method is entirely different. Rapidly but concisely she travels over the whole range of problems involved in rebuilding our towns, from the design of the house to suit the needs of widely varying types of occupation, the problems of roads, of open spaces, of transport, the location of industry, the planning of town and countryside, to questions of cost and maintenance. Her annotations are good, and discussion groups taking up this pamphlet should be enabled to arrive at a sound and well-balanced opinion on the policy and action that will be required.

Mr. Hardie's pamphlet (No. 3. "Is Britain a Democracy ?") is scarcely in the same class as the other three, but none the less should serve its end, though his bibliography is open to criticism as much too limited. It is longer than the others, but it covers its ground thoroughly and is likely to stimulate lively discussion when used intelligently. Of this no less than of the remaining pamphlets, it can be said that they should not disappoint the hopes of the Association for Education in Citizenship that they will play a useful part in ensuring that the inevitable changes in social arrangements and assumptions are faced in an atmosphere of co-operation and goodwill.

LAND UTILIZATION IN ENGLAND AND WALES

THE report which the Committee on Land Utilisation in Rural Areas, under Lord Justice Scott as chairman, has submitted includes the majority report and also a minority report by Prof. S. R. Dennison, which differs in outlook and its observations on policy rather than in the detail of the actual recommendations, particularly in regard to machinery and procedure, a note of reservation by Prof. Dennison and Mrs. H. Hichens and an additional memorandum on valuation and rating by the chairman, vice-chairman, Mr. H. S. Cooper, Mr. A. E. Monks and Mr. P. Robinson. The Committee was appointed by Lord Reith in October 1941 to consider the conditions which should govern building and other constructional development in country areas of Great Britain consistently with the maintenance of agriculture, and in particular the factors affecting the location of industry, having regard to economic operation, part-time and seasonal employment, the well-being of rural communities and the preservation of rural amenities. The terms of reference did not include Scotland.

The majority report is in three parts. The first reviews the present position, successive chapters dealing with the land and population, the countryside, the impact of town on country, the effects of urban growth on the countryside, the War and probable post-war trends and planning powers. The admirable chapter on the countryside describes the pattern of the countryside and its evolution, including the influence of agriculture and types of farming and factors determining farming systems, the origins of the landscape pattern and the changes during the last few decades, as well as the drift from the land and its causes. The Committee points out that the beauty and pattern of the countryside are the direct result of the cultivation of the soil, and there is no antagonism between use and beauty. The physical impact of town on country is then analysed, as well as the consequences which have flowed from the greater appearance of the townsman in the country, whether as a rambler, a motorist or a week-end visitor. A study of the effects of urban growth on the countryside leads to the conclusion that, on balance, more harm than good has been done to the countryside in England and Wales by constructional development before the War, while the broad conclusions reached as a result of the review of the developments of the pre-war years and the changes brought about by the War are that the former trends of constructional development, with some slight modifications tending to a greater diffusion into country areas, will, unless checked and diverted, reassert themselves after the War. A post-war building boom, possibly even more intensive than that which took place in the 1920's, if left to take care of itself, will lead to the same and probably worse evils than those which characterized the inter-war period. The evils to the social well-being of town inhabitants as a result of ill-considered or uncontrolled urban spread are now well known, and the evils from the point of view of the countryside were no less apparent in the years leading up to the present War. The future of the countryside will be profoundly affected by the choice between haphazard and planned constructional development.

This argument for the immediate establishment of the necessary machinery for planning and control is reinforced by a survey of present planning powers, both of the Town and Country Planning Act, 1932, under which the unwillingness of many local authorities to collaborate with their neighbours has been lamentably apparent, and of the Restriction of Ribbon Development Act, 1935, the weaknesses of both Acts being concisely indicated. Both failed for the same reason—the claims for compensation against the authority administering the Act. Assuming therefore that the policy of the Government includes the establishment of a Central Planning Authority, the Committee in the third part of the report outlines the machinery and procedure required for planning and development. The Government machinery for the formulation and execution of national planning is conceived as consisting of a standing committee of the Ministers concerned under the chairmanship of a non-departmental Minister of Cabinet rank, Government departments concerned with development, a Central Planning Commission and such *ad hoc* bodies as may be required to carry out functions not already covered by existing Ministers or other authorities or bodies.

The Central Planning Commission should consist of a full-time independent paid chairman, with ministerial status, and a number of part-time or full-time commissioners chosen on account of their special qualifications and knowledge as individuals of proved ability in their own spheres. The staff of the Commission should consist of Civil Service personnel, chosen with an internal knowledge of the departments with which the Commission will be in contact, and other persons, including some specialists, chosen for their knowledge of particular subjects and the prosecution of research. Outside London, the Commission should be represented by local officers to settle so far as possible all matters of local importance.

The duties of the Commission should include unified research and inquiry; the collection and correlation of information and the direction of research in connexion therewith; the formulation of national planning principles in accordance with directions received from the Minister, and the translation of national policy into concrete terms of national planning; the formulation and communication of general principles for the guidance of local planning authorities and the initiation, either direct or through the local officers, of schemes of national importance; and the approval or disapproval of plans submitted by local planning authorities and decisions thereon in accordance with Government policy. While much of the work of the Commission will be advisory, there should be a statutory obligation on all departmental Ministries to afford all requisite information to the Commission, and to consult with it and to consider its advice. Exceptionally, bodies with executive powers, for example, a National Parks Authority, may be set up where the policy of the Minister of National Planning requires executive action.

In regard to local planning, the report recommends that the local authorities continue to exercise their functions as planning authorities, but no longer without guidance, and it should not be possible for local authorities to refuse to co-operate in planning schemes. Local planning must be compulsory and not permissive. Normally, the primary local planning unit should be the county or a county borough and its surrounding area, or a comparable combination of local government units. Qualified personnel must be employed, and consultation between neighbouring planning authorities be compulsory. Local planning authorities should be freed from the restrictions in zoning agricultural land due to liability for compensation, and where they are carrying out their assigned part in a national plan, the expense should not fall on their own local financial resources.

In regard to procedure, the Committee considers that direct national action on broad lines will be required by the Central Planning Authority without waiting for the formulation and submission of planning schemes by local planning authorities. The work of determining the main types of land along the lines used by the Land Utilization Survey is part of the research which should be organized by or on behalf of the Central Planning Authority. The recommended procedure for controlling land use in country areas involves the national delineation of certain land areas; the local zoning of land similar to that adopted in present town and country planning schemes; and the consideration of individual cases in certain zones where such a course appears desirable.

In planning rural land, the majority report recommends that particular importance should be attached to agricultural considerations, and that land included in one of the categories of good land should not be alienated from its present use unless it can be clearly shown that it is in the national interest that the change should be made. Again, the majority report recommends that the power of compulsory acquisition of land by the State be exercised where required in the interests of national planning or for achieving that high degree of permanent efficiency in agriculture which vitally affects the essence of the problem. They recommend that the new 2½ in. to the mile maps be made available for all planning purposes, and stress the importance of adequate status and training of planners and architects. Great importance is attached to a very high standard of professional qualifications being required and maintained.

In the fourth part of the report, there is outlined a five-year plan for England and Wales, starting from the position as it will be after the War and not as it is at this moment, though between then and now the extremely important work of recording war-ime changes and of collecting and tabulating statistically and cartographically the developments now taking place must be completed. Research work carried out by the Planning Division of the Ministry of Works and Planning, the Farm Survey of the Ministry of Agriculture, and the Nuffield College Social Reconstruction Survey are regarded as essential parts of the war effort. A proper co-ordination of the research underlying national planning is an ssential function of the Central Planning Authority. While some of the essential research cannot be carried ut until the War ends, the Committee recommends that a plan be drawn up, consistent with the general olicy for continuous national planning, of work to be completed within five years.

Within the first year, the system of land classification for planning purposes should be agreed, and the standard procedure for co-operation between the appropriate town-planning officers and officers representing agricultural and rural interests laid down, the panels of architects and planners set up, the comprehensive investigation of electricity, gas and water supplies and the demarcation of national parks and natural reserves completed, and the National Parks Authority established. The Government should lay down a definite agricultural and food policy for at least five years, having regard to the increasing knowledge of nutrition and the national health. Within the five years there should be completed first town- and country-planning schemes to cover the whole of England and Wales, providing a full indication of the areas where industrial zones are or are not to be established, and satellite towns or new settlements located; secondly, a definite number of houses for rural workers; a full survey of all villages and hamlets to determine the existing facilities for village social centres (including playing-fields), and the drawing up of a plan for the provision where suitable of centres of the village college type, and the opening in all counties of a long-term building programme; programmes for electricity, water and gas, based on the survey made in the first year; the national park scheme, with hostels, etc., in working order; the determination and sign-posting of all footpaths and bridle-paths; rules, if any, for the control of access to the countryside, the use of commons and highways and other rights of way; the elimination of unsightly advertisements, petrol stations, etc.; and the registration of title. With all this, an educational campaign to promote better understanding between town and country should be carried on continuously.

This outline of the recommended five-year plan indicates how comprehensive are the recommendations of the majority report detailed in Part II and summarized in Part V. Some of these have already been outlined in describing the five-year plan. Others relate to forestry and arboriculture, where an extension of afforestation on poor land together with the establishment of foresters' part-time holdings and national forest parks are recommended, as well as enforcement by the Forestry Commission of the proper management of all woodland in the country. In regard to village institutions, establishment of a permanent advisory committee on village life and institutions is recommended, as well as the provision of adequate playing-fields for every village. The importance attached to housing, to the provision of electricity at no higher price to the consumer than in the towns, the extension of gas supplies to rural areas, to a review of the whole question of water supply, all undertakings for which should be brought under national planning control, has already been indicated, while other major recommendations cover industry in country areas and housing and planning in such areas, as well as such matters as aerodromes, defence works, roads and railways, advertisements and cemeteries.

In regard to the farmer, it is recommended that extractive industries should be subject to effective planning control, and that in principle no person or body should be allowed to work land for the extraction of minerals and leave it in a derelict condition. Legislation should be passed imposing an obligation on all those who derive benefit from the working of land for minerals to restore that land for agriculture or afforestation or other purposes within a short specified time after the land has been worked out. The dispersal and future use of war factories established in the countryside should be determined by the Central Planning Authority in conjunction with the other departments concerned. Linked industries should remain in existing urban concentrations or trading estates, and where light industries are brought into rural areas, they should be located in existing or new small towns. Production and storage units of public utility undertakings located in villages or in the open countryside should be subject to street planning control as regards siting and appearance. Rural trades and crafts should continue to be sited in small towns or villages and should be encouraged. No modern industry has been suggested which would provide seasonal or part-time employment for agricultural workers and their families, and appropriate bodies should be asked to make a special study of this problem. Before new towns are established in country areas, vacant or derelict industrial sites in existing towns should be fully utilized. New satellite towns, housing estates, garden cities and suburbs should be sited wherever practicable away from the better farm land, and due attention paid to agricultural considerations in their siting. Sporadic buildings in villages and rural areas should be controlled, and new villages and extensions of villages should be planned and should be so far as possible of a compact and closely knit character. All new villages and country towns should be situated away from main traffic roads though within easy access of them, and all existing villages and country towns which have main traffic roads running through them should be by-passed so far as possible. New buildings in country areas should use to the full all the possibilities which new materials and new building techniques have made available, though the buildings should be designed so as to harmonize with their surroundings.

THEORY OF X-RAY DIFFRACTION

By PROF. P. P. EWALD
Queen's University, Belfast

THE numerous books on the diffraction of X-rays by crystals all treat the subject with the view of introducing the reader to the methods for determining crystal structures. It is true that some presentation of the theory of optical interference cannot be omitted and that the various books go into this theory to varying degrees. But it is only v. Laue's recent book* which makes the optical theory of X-ray interference in crystals its main aim. In it, the usual methods of crystal structure determination are curtailed or omitted, since they involve more geometrical than optical discussion, once the reduced intensities are taken as known. Omitted as well is the description of experimental methods, as the emphasis of the book is on theory.

What variety and scope the subject presents will become apparent on comparing it with the corresponding theory of the diffraction of light by a plane optical grating. This theory consists of two parts: the diffraction by a single element of the grating (slit, wire or groove) and the action produced by the repetition of such elements. The first part is not important for most aspects of the effect of a plane grating, other than the distribution of intensities over the spectra of different orders. Its counterpart in X-ray diffraction is the theory of the atomic factor, and this brings the subject at once into the domain of wave-mechanical atomic theory.

The second part of the theory, the grating effect proper, is more involved for X-rays by the fact that they encounter in a crystal a three-dimensional grating. This fact leads to geometrical propositions concerning the main directions of diffraction which equal in beauty the geometrical constructions of the Fresnel-Hamiltonian crystal optics. Furthermore, the three-dimensionality of the crystal shape is carried over to the array of secondary diffraction maxima which surround each main maximum. The resulting complicated intensity distribution in space, modified by the 'crystal shape factor', is the three-dimensional generalization of the well-known one-dimensional diffraction function which determines the resolving power of a plane grating of finite width.

The most profound influence of the three-dimensionality is, however, to be found in the strong interaction of each element with all its neighbours; this makes the theory of diffraction a part of the major problem of the propagation of an optical field through the crystal, that is, part of the problem of refraction and dispersion by the crystal. The resulting 'dynamical theory' of X-ray diffraction is fully treated in Laue's book.

While these points still bear a correspondence to the problems encountered for the plane grating, there are three others which have no counterpart. The first of these is due to the thermal motion of the diffracting centres, which not only produces an unavoidable irregularity of the lattice but also endows each centre with a velocity leading to a Doppler effect of the scattered radiation. The second new point is the production of scattered radiation of incoherent character and of Compton-modified frequency. The last is connected with the possibility of generating, for example by electronic bombardment of the crystal, monochromatic radiation at the interior of the crystal; this radiation has been shown by Kossel to emerge preferentially in certain directions.

The aspects of the theory as enumerated determine the scheme of Laue's book. The author starts with the theory of atomic scattering along wave-mechanical lines, but in rather a novel manner. He first points out that the general theory of integration of Maxwell's equations permits the introduction of various forms of scalar and vector potentials. Now for the perturbation problem of finding the scattered radiation without blurring the distinction between the perturbing incident potential and the normal constitutiona potential of the atom, only one of these forms i suitable, namely that in which the fields derive from the vector potential cannot cancel those derive from the scalar potential. This is true for the aton as well as for the entire crystal, and the correct introduction of the potential is essential for the unity o method in treating atoms and crystals. The fu development of the method will be found in the paragraphs introducing the dynamical theory, where th wave-mechanical concepts are further related t classical Maxwellian theory. The existence of th Schroedinger current can be interpreted classicall as due to a changing polarization, and the polarizatio together with the electric field vector E can be con pounded to a dielectric displacement D. This is a in Lorentz's theory of electrons, except for the diffe ence that D is here a vector locally determined by th ψ-function for each electron, and not an averag value over a distribution of polarization unknown i detail. The distinction between E and D leads to th definition of a dielectric constant which for a cryst is a periodic function in space. The theory of diffra tion and of scattering is thus reduced to the proble of integrating the Maxwellian equations for tl propagation of waves in a medium of varying dielectr constant. These variations are determined, accordi to wave-mechanics, by the ground state of the syste as long as absorption is negligible, and by high states as well near absorption edges.

---

* Röntgenstrahlinterferenzen. Von Prof. M. v. Laue. Pp. viii+358. (Leipzig: Akademische Verlagsgesellschaft Becker und Erler Kom. Ges., 1941.)

The reduction of the problem of X-ray diffraction to wave-mechanics has been developed in papers by Laue and his co-workers Kohler, Moliere, Lamla, but it is given a more connected discussion in this book. Its main advantage is the uniformity of method in treating the scattering by atoms, molecules and crystals, and for the latter the foundation of the dynamical theory on the Fourier series for the electron density in the crystal.

Among the problems that have to be dealt with by the dynamical theory are the intensity of reflexion by a perfect crystal, the multiple reflexion resulting in a weakening (*Aufhellung*) or strengthening (*Umweganregung*) of the main reflexion, and the "lattice source method" of diffraction of Kossel. The latter has been reduced in a most elegant way by Laue to the established formalism of the dynamical theory by using an optical reciprocity theorem which relates the intensity received outside the crystal from a source inside it to the intensity created by an external source at the point of emission within the crystal.

Apart from the dynamical theory, the optical side of the theory of the temperature factor has been treated with great care and clarity by v. Laue. It is true that this theory remains on the level of the 'kinematical' theory of diffraction which includes only such effects as result from composing scattered wavelets derived from a single primary (incident) wave of given propagation. Instead, the treatment to be aimed at should be to study the propagation of an optical field, consisting of an indefinite number of waves of adaptable velocities, through the temperature-disturbed crystal, in the same way as it is done for the undisturbed crystal in the dynamical theory.

This combined thermal-dynamical theory has so far not been attempted. Laue's treatment is, however, superior to most previous presentations in employing a uniform method for discussing the temperature effect on the scattering by molecules and by crystals. In both systems the thermal displacements can be regarded as due to superimposed normal oscillations about the equilibrium position, and the independent co-ordinates of the system are its normal co-ordinates which perform simple harmonic oscillations of frequencies, say, ν_j. As a result of these, the scattered radiation can be expressed as a sum of components of Doppler-modified frequencies $\omega \pm p\nu_j$, where ω is the X-ray frequency, and p any integer. The intensities of the components are given by Bessel functions, the arguments of which are the 'roughnesses' produced in the reflecting plane by each type of lattice vibration. The main difficulty of the calculation lies in the fact that since the 'roughness' is of the order of the X-ray wave-length, the change of phase produced by the superposition of lattice vibrations is not simply the sum of the phase differences due to each vibration. The result of Laue's careful discussion is that wavelets of unmodified frequency ($p = 0$) are collected in principal and secondary maxima of the same directions as for a lattice without thermal motion; the atomic factors f_n have to be replaced by f_nD_n, where D_n is a Debye factor containing in its argument the mean square displacement of the nth kind of atom taken along the normal to the reflecting plane. All the background scattering is due to radiation of Doppler-modified frequencies $\omega \pm p\nu_j$ with $p \neq 0$, but the change of frequency is too small to be readily detected by experiment. In stressing the Doppler effect, Laue's theory of the thermal factor differs from the recent treatment on wave-mechanical lines given by Born and Miss Sarginson and others, but it seems unlikely that the results would be greatly affected.

As a second step, of purely dynamical, not optical, theory, the mean square displacements of the atoms, resolved along the normal to the reflecting planes, have to be calculated as functions of the temperature. Laue's book, stressing the optical part, does no more than outline this problem.

In the last third of the book, which deals with the dynamical theory, many interesting details will be found apart from the general approach which has already been described above. The theory of Renninger's 'multiple reflection' and of Kossel's 'crystal source method' are worked out; with respect to the former it seems a pity that no attention has been given to the experimental and theoretical work of Weigle and co-workers. A careful discussion is given of the transition from the dynamical to the kinematical theory in the case of small crystals. Another item is the dynamical theory for frequencies near to an absorption edge, following a paper by G. Moliere.

Anyone familiar with the subject will appreciate the sound physical and mathematical basis of v. Laue's book, and the many original and critical ideas incorporated in it. The reading is not difficult in spite of the fairly involved mathematics, and the limitation of the book to points of major optical interest excludes detail which may be necessary for the discussion of experimental data, but which would fatigue the general reader. It is to be hoped that the author may find it possible to complete a similar account of the theory of electron diffraction, a closely related subject on which he has been engaged for the last ten years simultaneously with the subject presented in this volume.

KEY METALS AND THE LOCATION OF INDUSTRY*

By PROF. C. B. FAWCETT
University College, London

FROM the beginnings of man's knowledge of metals up to about two hundred years ago, the number of known metals could be counted on his fingers. There were the 'noble', but not particularly useful, gold and silver, and such 'base' metals as copper, iron and lead, which made up for their baseness by being useful. Mercury also has long been known. Bronze and brass were known; though it is doubtful whether their composition and their relations to copper, tin, and zinc and antimony were understood before the eighteenth and nineteenth centuries. The number now known is five times as great. But, except for aluminium, the newer metals are chiefly of importance for their part in the formation of many alloys with the older metals. Iron is still by far the most important base of such alloys, and the most important of all the metals.

The effects on human society of so great an addition to available natural resources are both complex and far-reaching. But here I wish to note only some effects of the use of the key metals on the location

* Paper read at the Conference on Mineral Resources and the Atlantic Charter, arranged by the Division for the Social and International Relations of Science of the British Association, on July 24.

of industry, which is an important factor in the economic and social organization of a modern civilized community.

These key metals are used chiefly in forming, with iron, most of the many steels which are now known and used. Up to a century ago, the only important steel was carbon steel, which had been known to some extent for perhaps two thousand years. But though it was known, in the sense that it could be produced by the smelting of some forms of iron with some forms of charcoal, that knowledge was only empirical. Before the middle of the nineteenth century the making of steel on any large scale was still something of a gamble. The process could not be understood—and so controlled—until the sciences of chemistry and metallurgy had made considerable progress. Then came the systematic study of iron and steel. This led to a knowledge of the solvent powers of molten iron; and so to a study of the properties of the solidified solutions—the steels. Such investigation demanded large-scale organized research, and most of it dates only from the present century, particularly during and after the War of 1914–18. Not all the steels are of present importance. But some of them are so much so that they have caused a revolution in tool materials. There are now steels which are respectively harder, tougher, less corrodable, more resistant to softening at high temperature, etc., and so more efficient for particular purposes, than any formerly known. We have now better cutting steels than before, and others better for other purposes.

It is probably true to say that the sudden improvement in one tool material within this century is a change comparable to that from the ages of stone to the ages of bronze and of iron. Its social effects are not likely to be less than those of the first introduction of metals as tool materials.

The more important of these key metals include chromium, and cobalt, manganese, molybdenum and nickel, tungsten and vanadium—a list which is far from being exhaustive.

In relation to the location of industry, and their effects on it, it may be noted that these metals normally occur in quantities which are small in comparison to the ore bodies of the longer-known iron and copper, and they are found chiefly in rocks of Archean types; and so in areas away from the fertile lands of dense agricultural settlement and also away from the great coal deposits, which are not found in rocks older than the carboniferous. So the sources of the key metals are, for the most part, in remote and thinly populated areas. Secondly, the key metals are used in small quantities, very rarely forming as much as 10 per cent of a steel, and usually much less. So that where iron is needed in thousands or millions of tons the key metal is needed only in tens or thousands of tons. Thirdly, in its relation to industry, it is characteristic that the whole of a key metal used becomes part of the final product. The amount wasted in the process of manufacture is negligibly small.

Many of these metals are found in such a form that the metal itself is only a small proportion of the material mined. Hence there is usually a process of 'concentration' at, or very near, the mine. The location of the mine itself, and of this 'concentration', is of course determined by the place of occurrence of the ores. But once the concentrate is obtained, it is transported to existing centres of industry to be refined and then used; and it seems that the place of occurrence of the ores of the key metal has, in most cases, little or no influence on the location of the industry which uses it.

Let us consider, very briefly, some factors influencing the location of manufacturing industry, and their relation to these metals. Such factors may be grouped as primarily economic, or social, or political, though some may come under more than one of these heads.

The economic factors are chiefly those concerned with the needs for transport and power. In respect to the first, the materials to be used can be divided into (*a*) those which are wholly or mainly used up in the processes of manufacture, and (*b*) those which, like the key metals, form part of the finished product. The latter must, in all cases, be transported from their place of origin to the final user of the product; and usually it makes little difference to cost where they are stopped on this journey to undergo the transformation from raw materials to finished goods. There is, however, a difference according to whether the use is widespread or concentrated. In the case of the key metals it is mostly the latter; for the alloys containing them are built into tools most of which are used in industry (or armaments) and not spread widely in small lots. So there is, in general, an attraction of these materials to the regions of heavy industry, the location of which has been previously determined by facts independent of these metals.

The other chief economic factor is the power required in the manufacture; though this, especially when it is in the form of coal, might be classed as a material which is wholly used up in the processes of manufacture. There is thus a great saving in reducing the transport of such power. This was the attraction which, in the palæotechnic period, brought heavy industries to the coalfields; and it is still important, though the more recent electrical transmission of power has lessened the pull of the coalfields.

The chief social factors in the location of an industry are related to the amount and kind of the labour it needs. In this respect the key metals are easily classed. They are almost wholly used in industries, and sections of industries, which are dependent on highly skilled labour; and the products into which they enter go to similar industries. Hence the key metals come almost exclusively to regions of highly developed—and so generally of long standing—metal industries. By aiding the development of, and the demand for, skilled work, they tend to confirm the existing location of those industries. Up to the present, except for some Government armament industries as in Japan, practically all the key metals are used in the two great zones of established manufacturing industries in eastern North America and in Britain and Europe.

The political factors are very different in their effects. Here the dominant factor is that the key metals are essential to the armaments industry and to the making of tools which produce armaments. Hence, in a world of independent sovereign States, no State can feel itself secure or really independent unless it has within its borders a considerable armaments industry. In fact, no State which is not an important industrial power can, to-day, be an important political power. Thus the political influences on the location of industries are particularly obtrusive in relation to those in which the key metals are vital, and in recent years such political forces have been of primary importance.

The economic and social factors which tend towards the location of the industries using the key metals near the centres of older metal-working industries are further strengthened by the recent tendency—very prominent in steel-making—to an increasing use of 'scrap metal' as a raw material, which has long been practised with the more expensive metals. A note in the *Monthly Labour Review* of May, 1935 (p. 1155) states that in the U.S.A. "scrap iron and steel" formed 9·9 per cent of all the materials used in steel-making, and approximately half of that of the finished steel. These proportions may have increased under war conditions. They are likely to remain high, and to be applied to all metals, if we can attain a sanely conservative use of our metal resources. In that case we would regard the world's stock of a metal as a 'revolving stock'—to be used over and over and only replenished by 'new' metal to the extent needed to make good losses due to fair wear and tear and to provide for new uses.

'Scrap' is already a substantial part of the immediate raw material of these industries. But scrap is produced where metal goods are made and used; so that this part of the raw material comes back from the markets. Thus it tends to increase the pull of the market on the location of the industry, and so to strengthen the factors which keep it in the regions of developed industry.

The increase in the number of different materials needed by an industry necessarily lessens the relative importance of each one of them. So the complex industry, by spreading its dependence over a wider range of natural resources, becomes less dependent on the location of any one of them; and as the factors which influence its location thus become more numerous, the possibilities of effective intervention to control that location become greater.

MINERALS, OLD AND NEW, FROM THE SEA*

By Dr. E. F. ARMSTRONG, F.R.S.

HAD I been writing a book on the subject I should have first described the crust of the earth, some 20 miles in thickness, and then gone on to point out how, by the processes of destruction and denudation, this is continually being washed first into the rivers and finally into the sea, much of it going into solution. As the poet tells us, "even the weariest river winds somewhere safe to sea". The quantity of any one constituent of the crust in a thousand parts of sea-water is infinitely small and indeed many are only detectable by the most refined methods of the chemist, but there is so much ocean in the world that in the aggregate it contains many tens of thousands of tons of even the very rarest constituent.

In the past, but for one constituent—common salt—sea-water has never been regarded as a source of raw materials for industry. To-day three other essential substances—potash, bromine and magnesium salts—are being extracted in considerable quantity from the sea by methods which are both novel and interesting. Such methods open up an avenue to the winning of other even scarcer but coveted minerals.

Common salt is an essential for both man and beast, and those countries which lack it go to any end to obtain it. In New Guinea, for example, it was used by traders not so long ago as the best currency for the purchase of native goods. In Britain and in Europe there are large deposits of pure salt resulting from the drying up of inland seas in past geological ages. The Dead Sea in Palestine is an example of such a sea in process of evaporation. At Stassfurt in Germany the sea dried up entirely, so that both the salt and the mixture of potassium and magnesium chlorides, sulphates and bromides remain in the earth, though, strange to say, there is no iodine.

The composition of the ocean varies considerably in different places and at different depths. The salinity expressed as total salts per 1,000 parts of sea-water varies from a minimum in the southern part of the Indian Ocean, 33·01 parts, to a maximum from the middle of the North Atlantic, 37·37 parts.

In hot countries the sea is led into basins and allowed to evaporate in the heat of the sun until first the calcium sulphate and then the salt crystallizes: the salt is impure but suffices. The bittern or residue is of no commercial value though it has been further treated to obtain potash in an Italian colony.

The export of salt from England has for long been a significant part of our overseas trade. Together with the chemical products made from it, for salt is one of the foundations of chemical industry, it has helped to make Liverpool one of the world's greatest ports.

The exploitation of any particular source of a mineral is determined by economic considerations. Bromine affords a good example: so long as the demand for it was relatively small, the Stassfurt monopoly maintained it at a high price. When it was required in very large amounts to make 'ethyl', other cheaper sources had to be found. One of these is the Dead Sea, which is a half-evaporated inland sea situated in a climate where there is more evaporation than precipitation. As the concentration of salts at the bottom of the lake is greater than that at the surface, the solution is pumped from depth, concentrated and processed to obtain potash salts and bromine, thus affording a British Empire source of these minerals. There are similar inland lakes in the United States. The Americans went to the sea itself for their bromine, having devised a simple method of extracting the traces of bromine from very large quantities of water. At first they fitted up a ship as a floating chemical factory so as to ensure new water all the time. Later the factory was put on land, the effluent water being run to the other side of an isthmus so that it never mixes with the untreated incoming water. It requires 4,000 gallons of sea-water to yield a pound of bromine, so that a factory making only 50 million pounds, say 25 thousand tons, a year has to pump a great deal of the sea through its apparatus. The sea-water is made of a particular acidity, the right amount of chlorine gas added, and the free bromine so liberated is blown out by a stream of air counter current to the water which is falling down high towers with wooden packing. It is absorbed in soda solution, forming bromides and bromates. The process is continuous and automatic and under instrumental control: it is one of the triumphs of modern chemical engineering design and construction.

---

* Paper read at the Conference on Mineral Resources and the Atlantic Charter, arranged by the Division for the Social and International Relations of Science of the British Association, on July 25.

Though in practice the recovery of magnesium metal from sea-water involves comparatively simple operations, it is far from being an easy task economically to utilize a raw material which contains about 1 part of magnesium in 800 of water. Quite unusual chemical engineering methods, equipment and control had to be invented. At the most successful and largest plant use is made of milk of lime, made from large deposits of fossil oyster shells found in the vicinity, to precipitate magnesium hydroxide from sea-water which has been freed from extraneous matter. The hydroxide is collected in special filters and converted into magnesium chloride, using for this operation a 10 per cent aqueous solution of hydrochloric acid which is largely derived from a latter stage of the operation. The magnesium chloride is evaporated and dried until anhydrous, when it is electrolysed in suitable cells to produce metallic magnesium: hydrogen chloride is evolved from the cells. Natural gas is used as a source of power; the effluent water is discharged seven miles from the intake into a current of sea-water which is always in the same direction.

Such, in a paragraph, is a description of a factory which is full of new methods and devices. Magnesium, the lightest of metals, cost a sovereign a pound in 1915 and barely a shilling last year. It is expected that the capacity of a single sea-water plant will be increased to 100,000 tons of metal by the end of this year, which represents an incredible number of gallons of sea-water.

At the same factory, though in a separate plant, bromine is being extracted, and the acid effluent from this mingles with the alkaline effluent from the magnesium to make a largely neutral return flow to the sea.

Magnesium metal was first made around 1869 mainly as a source of high-intensity light for photographic purposes. Later on, sundry uses in fireworks came along. It awaited war to start its use in aeroplanes and in incendiary bombs.

Magnesium in combination is one of the most abundant elements on the earth's crust. The most favoured source is magnesite, which in particular is used for refractories. Other sources are dolomite, where it is associated with carbonate of lime and carnallite. If the metal is to be made by electrolysis, hitherto the favoured process, the magnesite has to be converted into chloride by briqueting the calcined material with carbon and binding substance and exposing to the action of chlorine in an electric furnace. Since in the course of electrolysis chlorine is involved, the process becomes in theory cyclic, although in practice there is waste through formation of hydrogen chloride.

There are also competitive thermal methods for the reduction of magnesite to the metals. The two principal reducing agents are calcium carbide and ferro-silicon. The retorts are either heated externally by gas or internally by radiators. A good vacuum is maintained, and the metal distils in a pure form, only requiring melting. These processes can use dolomite in place of magnesite, merely at the expense of a smaller yield. There are many varieties of these processes, especially in the United States.

Direct reduction by carbon requires a very high temperature, for which an arc is necessary, and the vapour must be rapidly chilled in order to prevent the reversal of the reaction with carbon monoxide, regenerating the oxide. In the original Radenthein process this was done by a jet of compressed hydrogen, cooled to a very low temperature. The magnesium was precipitated as a very fine dust, which had to be melted by high-frequency current without exposure to air. Although much has been heard of this process, it does not seem to have had much success. The Permanente Corporation in California uses natural gas as the cooling agent. The dust is collected, mixed with oil to a dough and distilled. The Ford Co. uses oil as the quenching agent, and a pilot plant of the Dow Co. is using molten lead, from which the magnesium can be distilled.

Magnesite made from sea-water is proving a useful raw material for refractories. If calcined dolomite, a domestic British mineral, is used instead of milk of lime to precipitate the magnesium from sea-water, a double purpose is served and additional magnesium hydroxide obtained.

It should perhaps be mentioned that the production of magnesium metal and of magnesite in the years before the War exceeded the demand: many new uses for the metal will require to be found to absorb the output when peace returns.

Certain minerals reach the sea either from sewage or by the leaching out of cultivated lands. While these in the aggregate total far less than what is produced by denudation, they are of importance because they represent those constituents which are of primary value to man. One of these is phosphate, of which the mineral deposits are limited in amount and likely to become exhausted. Many of the agricultural soils of the world are definitely short of phosphate and their crop-bearing qualities impaired in consequence. It has been calculated that the sewage from 5 million people is equivalent to 17,000 tons of rock phosphate in a year and this quantity is equal to the amount of phosphate in the bones of the annual export of meat from New Zealand. The population of Great Britain discards as sewage yearly the equivalent of 150,000 tons of rock phosphate, most of which reaches the sea.

An estimate of the annual losses of phosphate from all sources to the sea in the United States amounts to the equivalent of 61 million tons of rock. The world's consumption of phosphate rock is said to be 18 million tons.

There is clear evidence that phosphate must be accumulating in the sea, unless it is somewhere being concentrated and deposited.

The chemist is already searching for materials capable of selectively absorbing and retaining substances present in small quantities in large volumes of water. Such base-exchanging materials are widely used in the softening of hard waters and make it possible to take a good deal of the salt out of sea-water, though not enough to make it drinkable by distressed mariners. What is wanted soon is a material which will extract the phosphates and concentrate them to an economic point; the discovery of such an agent should be feasible and may be imperative a generation or so hence.

The advantage of the sea as a source of minerals is that there is free access to it for any country which has a coast-line. Its use, therefore, comes under the fourth clause of the Atlantic Charter. The knowledge of its constituents and its exploitation in the service of man depends upon the progress of scientific inquiry.

The costs of pumping are less than those of mining: on the other hand, the ingredient desired, which may constitute 50 per cent of a land mineral, may be present to the extent of much less than 1 in 1,000 parts of sea-water. A technique of handling large volumes at low cost has to be elaborated before the sea can become a source of minerals.

It is of interest that some plants and animals have the power of concentrating certain of the ingredients of sea-water. Iodine, for example, is present to the extent of 0·001 per cent, whereas the dry matter of deep-water seaweed such as Laminaria contains 0·5 per cent. Kelp, or *varech*, as it is called in France, has been used for many years for the commercial extraction of iodine, even though this practice cannot compete economically with the production of iodate from the caliche in Chile. Certain coral species are said to contain up to 8 per cent of iodine, and it is present here and in the bath sponge in the organic state as di-iodo-tyrosine.

To complete the story we should cite another natural organic halogen compound, Tyrian purple, the purple dye containing bromine derived from a mollusc, which was used to colour the togas of the Imperial Roman Emperors.

The seaweed moves lazily to and fro at our feet as the tide rises; we know what iodine signifies to us though we are without knowledge of what it means to the seaweed.

The oyster concentrates copper, which is another material which may some day be scarce and have to be obtained from the sea. It has been estimated in the United States that 200 tons of copper are lost in sewage every year per million people, together with 50 tons each of such metals as manganese, lead, aluminium, and titanium.

There is an interesting organism, a holothurian or sea slug, found off the Cornish coast, which has the power of concentrating vanadium in its structure, though the quantity in the neighbouring rocks is very minute.

A balance sheet between land and sea is instructive as showing the loss each year of considerable quantities of the rarer minerals. They must either be accumulating in the sea and be available for recovery, or being deposited to form new areas of sedimentary rocks.

It is on record that for a whole month the very minute traces of gold in sea-water were recovered at the great plant which extracts bromine. The gold was there, but at a cost several, stated to be four, times its value, so that the mines of South Africa need not feel anxious.

Probably many experiments are in hand to extract coveted minerals from the sea. The chemist can do it, but at a cost which may not be competitive with a land source provided that this is accessible. The way to deal economically with large quantities has been shown. To solve such problems three things are essential: first, skilled chemists and chemical engineers, products of the universities; secondly, immense quantities of cheap electric power; and thirdly, a cheap source of heat. A country unable to provide any of these will fall behind in the race to produce even if it has 'free sea' available.

OBITUARIES

Prof. E. Fawcett, F.R.S.

THE death on September 22 of Edward Fawcett has taken away from British anatomy yet another outstanding personality. A fine figure of a man, his carriage was always firm and erect, even in old age; and this bodily vigour was the physical counterpart of a robust and active mind.

Born in 1867, he graduated M.B., C.M., at Edinburgh in 1889, and his interest in anatomy was already shown in his student days, for he was demonstrator of anatomy in the School of Medicine for two years before he qualified. He spent three years at the Yorkshire College, Leeds, and after this brief interlude proceeded to his permanent home in Bristol. In 1893, at the age of twenty-six, he was appointed professor of anatomy in University College, Bristol, and in that capacity he served until his retirement in 1934, when he was made emeritus professor. For a large part of that time (1905–34) he also served as Dean in the Faculty of Medicine. For practically forty years, therefore, he was associated with the Bristol Medical School as a whole, and the Anatomy Department in particular, and in the development of both he took an exceedingly active part. He was elected a fellow of the Royal Society in 1923.

As an anatomist Fawcett was held in high esteem by his colleagues. He was successively vice-president of the Anatomical Society of Great Britain and Ireland (1913), treasurer (1914–25), and president (1927–29). At the Budapest International Medical Congress (1909) he was president of the Anatomical Section.

From a review of an extensive list of published papers, Fawcett's work may be seen to fall, with some overlapping, into four main periods. In the first period he was interested in bones and joints generally, but the interest gradually narrowed down to problems of bone growth and formation of epiphyses. This second or epiphyseal period passed over to the third, in which interest was focused more especially on the development of individual bones of the skull. This led, naturally, to the fourth and most important period, when he published his researches on the growth of the mammalian chondrocranium. It is the work done in this fourth period which constitutes his most important and fundamental contributions to biological science.

During 1917–23 he published in rapid succession detailed accounts of the primordial cranium of a number of mammals: Microtus (1917), Erinaceus (1918), Poecilophoca (1918), Miniopterus (1919), Tatusia (1921), Xerus (1923), and Homo (1923). All his work was marked by scrupulous honesty and an unremitting attention to detail. Both his histological and reconstruction work were of a uniformly high technical order.

Briefly to epitomize Fawcett's work, one may say that he enlarged our knowledge of the development and morphology of the bones of the facial skeleton, and made fundamental and extensive contributions to our understanding of the detailed anatomy of the mammalian primordial cranium. His researches under this head are classical, and will remain as a permanent contribution to vertebrate morphology. Various pieces of lesser work, such as those on the development of the clavicle, the epiphyses of the axial skeleton, and the ossification of the sacrum, also constitute a lasting addition to our knowledge of osteology.

However, Fawcett possessed such a superabundance of energy that his anatomical labours, considerable as they were, by no means exhausted it. In 1919 he founded the Bristol Spelæological Society, and held office as president from its foundation until 1936. He published numerous reports on human skeletal remains submitted to him for examination, and indeed at the time of his death two such reports were awaiting publication, one dealing with remains associated with a beaker at Corston, Somerset, the other with some human bones from a Roman stone coffin exposed during the recent air-raids on Bath.

During his latter years, Prof. Fawcett was engaged in work of an archæological nature, in which he took great delight. As in his anatomical, so in his archæological work, he was influenced by two factors, the consideration of form and of development. He made a study of the ancient chairs to be found in Bristol and the surrounding counties, and arranged them according to their structural evolution. The same principles made him an accurate student of medieval architecture, for he made detailed observation of mouldings and other architectural features, and so was able to fix the date of a building or part of a building with authority.

He made complete lists of the achievements of royal arms in churches in the counties of Somerset, Gloucester and Wiltshire, and the City of Bristol, and he knew the arms of every family living within thirty miles of Bristol. His eye for detail led him to be the first person to record the anthropophagous figures which appear, often at a great height from the ground, on the external fabric of some churches.

Prof. Fawcett leaves a widow, a son, and a daughter.

J. M. YOFFEY.

Dr. Leonard Klatzow

THE death of Dr. Leonard Klatzow occurred on September 22 at the age of thirty-five. Dr. Klatzow was educated in South Africa, and came to England in 1930 as a Rhodes Scholar, obtaining his D.Phil. after three years' research work at the Electrical Laboratories, Oxford, during which he published several valuable papers in collaboration.

In 1934 Klatzow entered the research laboratories of Electrical and Musical Industries, Ltd., at a time when experimental development of high-definition television was beginning. The successful establishment of the London Television Station owed a considerable part to the improvements arising out of his work on photo-electric surfaces and allied subjects; among his colleagues he acquired an enviable reputation as a master of this difficult and delicate art. He maintained, as is not always easy in an industrial laboratory, a close contact with pure science, and was always quick to see the value of academic discoveries for the solving of practical problems. His work, largely unpublished, did not receive the wide recognition it deserved, but there is no doubt that a career of increasing distinction was opening before him.

His lively and generous personality made him a particularly agreeable colleague, at once stimulating and sympathetic, and led him to take a keen interest in the welfare of those around him, especially of the junior staff under his care. The shock of his loss was keenly felt when, at the end of a period of especially intense work, he died suddenly, of a long-standing but unsuspected heart weakness, literally at his post of duty.

B. M. CROWTHER.

THE secretary of the Association of Scientific Workers writes:

The name of Dr. Leonard Klatzow will always be associated, by a large circle of friends and fellow-workers, with the renaissance of the Association of Scientific Workers in recent years. He joined the Association in 1936, at the end of a public meeting held in the Imperial College of Science on "Defence and the Responsibility of the Scientist", and immediately threw himself wholeheartedly into its work. Nobody who met him failed to be infected by his enthusiasm for the Association and the ideas it stood for, which gave full scope for his sense of responsibility to his fellow scientific men and to the community as a whole. His lively imagination, methodical mind and personal charm admirably fitted him for this work, and within a few months he was elected to the executive committee and appointed honorary treasurer, a post which he held for more than three years. In two major enterprises at least he played a leading part, namely, the setting up of the Scientific Films Committee, and, later, of the London Scientific Films Society; and the complicated negotiations which led to the establishment of the Unemployment Benefit Fund for scientific workers.

NEWS and VIEWS

Soviet Scientific Work on Potatoes

A LONG cable has been sent by Prof. Lysenko, president of the Lenin Academy of Agricultural Sciences, to Sir John Russell, chairman of the Anglo-Soviet Scientific Collaboration Committee, describing recent results of Soviet scientific work on the potato crop which in the U.S.S.R., as in Great Britain, is now of very great importance as human food. The message begins by stating that the Odessa Institute of Genetics and Selection, of which he was for a long time director and where much of this work was begun, had been evacuated before the Germans captured the city. The investigations now being made under Lysenko's general direction by various scientific bodies, like all other scientific investigations in the U.S.S.R., are exclusively directed to the war effort; in this case to help the Collective and State farms increase the output of food and raw materials. Genetics, he says, is the science dealing with the nature of the living organism and its reactions to various environmental influences at different stages of its development. The better the laws of inheritance are understood, the easier it is to govern the nature of the plant organism and modify it in any desirable direction, thereby creating new plants possessing characters useful to man.

War conditions have made it necessary greatly to increase the area under potatoes in the U.S.S.R. because they furnish more food and industrial raw material per acre than any other crop. The difficulty arose, however, that supplies of 'seed' were insufficient to allow of much expansion. The shortage was overcome by using potato tops in place of seed, and methods for their preparation and planting were elaborated. In 1942 a total of 150,000 *ha* were thus planted in various parts of the south-east and centre of the U.S.S.R. and the yields were not inferior to those of potatoes planted in the usual way, and in regions where ring rot is prevalent plants grown from tops were less liable to the disease than those grown from seed. During the winter, extensive preparations are being made to collect potato seed material from Government and public vegetable stores and from private houses to ensure considerable enlargement of next year's potato area, and meanwhile the scientific workers are continuing work on collection of the tops and on their storage and preparation for planting. A request has been sent to Lysenko for details of the methods adopted.

Another method of increasing production in the southern regions, based on Lysenko's own work, is to arrange for two sowings of potatoes in one season. The old method was to sow in April, but the high June temperature led to poor crops of small tubers. The difficulty was overcome by planting in July; the crop is not large but as seed it is much better than the original seed, and, planted in the following April, it gives considerably higher yields. Seed for the July planting, however, cannot in the hot southern regions be kept over from the previous year; on the other hand, the freshly gathered seed does not readily sprout; a period of rest is necessary. Investigation showed that the length of this period depends on external conditions, particularly on the extent to which air can gain access to the plant nutrients contained in the tuber. Access of air is prevented by the skin, and when this is removed sprouting rapidly occurs. The technical problems associated with the large-scale application of this simple device have been worked out, and during the summer of 1942 experiments were made on collective farms and individual plots in irrigated areas of Central Asia, the results of which will enable the potato area of the southern regions to be greatly expanded in 1943. In conclusion, Prof. Lysenko stated that the problem now confronting us is to make the utmost use of our knowledge of the laws governing the development of plants so as to obtain he largest possible yields of the best quality crops from our fields.

Reconstruction Research

The third number of *Agenda* (London: Oxford University Press. 6*s*. quarterly) is notable for the aluable article on "Reconstruction Research con- ucted in Britain by the European Allies", by Ethel J. Lindgren. This article contains almost the first full account of the origin and character of the London International Assembly established as a result of the initiative of the League of Nations Union in the ummer of 1941, for purposes of study, discussion and a free exchange of views as private individuals nd not as representatives of Governments or parties. Of the five commissions established in November 941, only the first is concerned with a war-time roblem, namely, political warfare. The second deals with the trial of war criminals and to the third was legated future international organization and curity against war, and to the fourth social and onomic reconstruction. By the end of January 942, four sub-commissions had been appointed, ealing with collective security, international organ- ation, economic and financial problems and labour and social questions. The fifth is a joint commission of the London International Assembly and the Council for Education in World Citizenship on the place of education, religion and science and learning in post-war reconstruction. The last to be set up, its membership is large and keen.

No section of the London International Assembly constitutes purely or mainly a research organization, but it provides allied research workers, statesmen and responsible persons interested in international affairs with a focus and a forum where the fruits of research and trends of thought and policy can be brought together. The need for documentation and information is supplied to some extent through facilities afforded by the Royal Institute of International Affairs at Chatham House, and a liaison officer maintains contact between the work of the two organizations. The Allies can, moreover, draw on research carried out by their Governments and on a number of other institutions which are described. These include the Allied Post-War Requirements Bureau, the scope of which was indicated at the Inter-allied Government meeting at St. James's Palace in September 1941, and groups like the New Europe Circle, the membership of which is drawn from about nine European countries, including Civil servants, business men, engineers, students and journalists.

Brief reference is also made to the work of the National Institute of Economic and Social Research, the Nuffield College Social Reconstruction Survey and to various branches of the work of the Royal Institute of International Affairs. The paper includes accounts of various allied institutions such as the Belgian Commission for the Study of Post-War Problems, the Czechoslovak Research Institute, Fighting French Service d'Études de Documentation et de Liaisons, the Statistical Research Section of the Greek Ministry of Finance, official research under the Ministry of Justice, Luxembourg, the Study Group for Reconstruction Problems of the Netherlands, the Polish Research Centre, the Jugoslav Post-War Reconstruction Committee and research carried out by a number of Norwegian ministries, the co-ordination of which is now being discussed. The same number contains a review of research concerning some post-war domestic problems of the United States, which gives an account of the activities of the National Resources Planning Board. Seven fields of exploration as elements of a post-war programme have been suggested by the Board, covering demobilization, public works, industry, expansion of Service activities, security, finance and international activities.

Post-War Planning in the United States

A pamphlet on post-war planning entitled "After the War—Full Employment", by A. H. Hansen, which has been issued by the National Resources Planning Board, suggests that the American Government is making systematic attempts to prepare its people for post-war problems. It is also of interest as indicating the present outlook in the United States on post-war problems. While stress is laid upon the importance of retaining freedom of enterprise, freedom for collective bargaining and for co-operative action, as well as of choice of occupation, the importance of planning for full employment and to prevent a post-war depression is recognized. A shift towards a higher consumption economy is visualized. Points in a Government programme for this purpose include extensive research in industry, in the universities and in Government bureaux to develop new products and processes, the improvement of educational standards and the technique of production and distribution and of transport, building and public health.

The expansion of expenditure on public welfare, including old-age pensions and family allowances, is suggested, and the importance for international co-operation of pursuing internal policies designed to promote active employment as well as for the development of backward countries and for implementing ways and means to open outlets for foreign investment, promote world trade and the world-wide use of productive resources is recognized. With regard to the war period, a policy of high income and excess profits tax with a broadening of the individual income-tax base and steeply graded surtax-rates is advocated, as well as the part-payment of wages and salaries in defence bonds and a sharp increase in excise taxes on commodities competing with the war programme. In the post-war period a policy of retaining the progressive tax structure and broadened tax base with a major emphasis on the individual income-tax and less reliance on the corporate income-tax is suggested, together with a sharp reduction in defence consumption taxes and adequate plans by private enterprise for investment in manufacturing plant and equipment, railroads, public utilities and housing.

The Third Earl of Rosse and his Telescopes

MR. M. A. ELLISON has described (*J. Brit. Astro. Assoc.*, **52**, Sept. 8, 1942) the celebrated experiments of William Parsons between 1827 and 1845 for the improvement of reflecting telescopes. The earlier workers in speculum metal had jealously guarded their secrets of grinding and polishing, and each step in the process had to be established anew by experimenters. The earliest researches of Parsons were undertaken to determine the composition of speculum metal, which should possess the qualities of whiteness, high reflectivity, and resistance to tarnish. It was found that the conditions were best realized in an alloy of four atoms of copper to one of tin, and specula differing to a slight degree from this proportion of the alloys were found to dim rapidly, though they were quite brilliant when polished. Unfortunately, this alloy was liable to shiver at the slightest blow or sudden temperature changes, and attempts to cast it in disks more than about a foot in diameter were abandoned.

A description is given of the different telescopes—the 3-ft., the 6-ft., and the 18-in. reflectors—and also of their mountings. There was a general impression that the 6-ft. reflector had an altazimuth mounting. Actually, the movements of this telescope were equatorial, but they were limited to one half-hour on each side of the meridian. It is interesting to notice that γ_2 Andromedæ was used as evidence of its defining power. Robinson records that he saw the system distinctly, as two neatly separated stars, under a power of 828. The separation at this time (1845) was about 0·5″. The paper concludes with a list of assistants at Birr Castle Observatory and a short account of their work.

Indian Precious Stones

THE Geological Survey of India has recently commenced the publication of a series of Bulletins of Economic Minerals as a war-time measure to direct attention to India's mineral resources. Those issued in 1941 deal with chromite, strontium minerals, phosphates and clay, and several others are in preparation. No. 6 (1942), "Indian Precious Stones", by Dr. L. A. N. Iyer, is a useful pamphlet of fifty-four pages, with two plates illustrating the mining of ruby at Mogok in Burma. It rather gives the impression of a hasty compilation from scattered sources of information; but some additional matter is given relating to the Mogok "stone tract", where the author was engaged in the production of the Geological Survey maps. There, in addition to ruby, a considerable variety of minerals of gem quality has been found. Apart from these, and the sapphire of Kashmir and the many gemstones of Ceylon, there are really few occurrences of importance in India proper, except for semi-precious stones such as agate and almandine garnet.

At one time, however, India was the only known source of diamond, and many of the famous stones found centuries ago are of Indian origin. (One of these, known as "The Moon of the Mountains", was sold by auction in London in August 1942 for £5,200.) At the present time the production is very small, averaging for the years 1929–33 less than 1,500 carats (300 grams) and valued at 74,040 rupees (£5,555), the bulk of this coming from Panna State. It would be interesting to know how many persons, working by primitive methods in small and scattered pits, were engaged in producing this handful ($\frac{2}{3}$ lb.) of small diamonds. They would be of no use in the trade as industrial diamonds. India is actually a large importer of diamonds for jewellery purposes. At one time India was also the sole producer of corundum (of which ruby and sapphire are colour varieties of gem quality) for abrasive purposes, and in fact the name corundum is of Indian origin, but the present output is again very small.

Refrigeration of Fish in Australia

AN account of the application of refrigeration to the Australian fishery industry has been published by the Council for Scientific and Industrial Research (Commonwealth of Australia: Division of Food Preservation and Transport. Circular No. 4.–P, Melbourne 1, 1942). This is written in non-technical language and has been prepared to serve as a guide to the fish industry on the basic refrigeration requirements. As the result of a survey of the important fishing centres along the south coast of New South Wales and some centres in Victoria and Tasmania, it was found that it was possible to catch in eastern Australian waters considerable supplies of fish suitable for an important canning industry as well as for a substantial trade in fresh fish. Serious difficultie must, however, be overcome before any great expansion can take place. These notes are issued as a guide to future development based on the necessity for preserving fish by refrigeration to meet the requirements of a large and stable industry.

Tin Economy in Cable Jointing

A NEW type of wipe or fillet joint is described by J. T. Lowe (*Bell Lab. Rec.*, **20**, No. 11, July 1942) which makes it possible to meet the essential requirements for a wiped joint using far less solder without the necessity for a new wiping technique. Essentially, the new method consists of carefully beating in the cable sleeve ends to the proper shape to facilitat formation of a satisfactory fillet of solder and to obviate rounding out the sleeve ends with solder

Tests of strength, resistance to fatigue and gas-tightness show the new joints to be fully as good as the old. The wiping technique is somewhat simpler and is well liked by jointers. The adoption of the new technique reduces the amount of tin the Bell System would ordinarily need for wiping solders by more than 60 per cent.

Distribution of the Stars

DR. BART J. BOK, of Harvard, has made a report (*Sky and Telescope*, August) on one of the first results of work by the so-called "star-counting circuit", which is an informal organization of several observatories in the United States and other countries. A search was made for comparatively unobscured regions along the Milky Way, and several fields have been discovered in which the light of the distant stars is only slightly dimmed by the absorption of interstellar matter. The most notable clear regions are in the constellations of Cepheus, Auriga, Monoceros, Carina and Centaurus. In the portion of the Milky Way which lies between the southern Coalsack and Cygnus, in which the star clouds of Sagittarius and Scutum fall, there are no regions which are relatively unobscured. Even for the brightest patches in this section the light of stars at 3,000 light years from the sun is dimmed by a whole magnitude. It appears that the stars of different spectral classes are not well mixed in our part of the Milky Way. It is remarkable that there is a rapid initial decrease in star densities for all classes in the direction of the galactic nucleus, and at 1,000 light-years from the sun the densities are very low. Higher densities are not found for the central regions until we reach three to five thousand light-years from the sun.

Bibliography of Seismology

THE present number of this important bibliography (13, No. 11, January to June, 1942), published at the Dominion Observatory at Ottawa by Ernest A. Hodgson with the assistance of four collaborators, maintains its previous high standard. There are seventy-seven items culled from world-wide sources covering topics from the strength of rock materials to world structure. Many items concern patents for geophysical prospecting such as item 5326, Williams, P. S., "Seismic Exploration Method", U.S. Patent 2,253,358, Aug. 19, 1941, and Beers, R. F., "Means for Analysing and Determining Geologic Strata", U.S. Patent 2,249,108, July 15, 1941. Items from NATURE and *Science News Letter* are included. There has been some discussion recently concerning the geology of the beds of the oceans especially near shore-lines. This enhanced interest is mirrored in item 5313, Jones, O. T., "Continental Slopes and Shelves", *Geographical Journal*, 97, No. 2, 80–99 (London, Feb., 1941); and in item 5341, Shepard, Francis P., and Emery, K. O., "Submarine Topography off the California Coast", Geological Society of America Special Publications, No. 31, 171 pp., 4 charts, 18 pl., 42 fig. (New York, 1941). Reginald A. Daly made a contribution to NATURE concerning "Glaciation and Submarine Valleys" on Feb. 7, 1942 (pp. 156–60), item 5291.

Earthquakes Registered in New Zealand

DURING June 1942, eight large earthquakes were registered by the seismographs at Wellington, Auckland, Christchurch and Arapuni, according to Provisional Bulletin No. P–124 of the Dominion Observatory, Wellington. Two prominent shocks were on June 6 with epicentre east of the New Guinea region and focal depth about 100 km., and on June 24 at Wairarapa. Thirty-one local earthquakes were recorded during the period, including the Wairarapa shock mentioned above. This reached intensity 7 on the instrumental magnitude scale (New Zealand Bulletin P–104, p. 3) and was followed by nine principal aftershocks and about 418 minor shocks. Several of the aftershocks reached intensity 4½, and on June 25 an earthquake of intensity 4 was felt at Hokitika.

Research in Industry

IN connexion with the discussion of the relation of academic and industrial scientific research, Mr. Foster Sproxton has raised the question, in correspondence, of the position of the smaller industries which have no research associations. They may have problems arising in chemistry, physics, the various branches of engineering, or problems involving the biological sciences, outside the field of the regular scientific staffs employed at the factories. Guidance in the choice of an academic consultant would be of the greatest value in such industries. Mr. Sproxton believes that some kind of panel of academic scientific workers willing to assist in the solution of industrial problems would be of service, and suggests tentatively that such a function might form part of the activities of the Central Register.

Dr. Gustav Retzius

DR. GUSTAV MAGNUS RETZIUS, a celebrated Swedish biologist, was born at Stockholm on October 17, 1842, the son of an eminent anatomist. He received his medical education at Uppsala and Stockholm, and qualified at Lund in 1871. Six years later he became 'extraordinary' professor of anatomy at the Caroline Institute at Stockholm. In 1889 he was appointed full professor, but resigned in the following year in order to devote himself entirely to scientific research, particularly in anatomy and anthropology, for which he travelled extensively in Europe and America. Most of his work was concerned with naked eye and microscopical anatomy, but he also made studies in embryology, anthropology, zoology and botany, so that he was a biologist in the fullest sense of the term. Between 1876 and 1906 he published six illustrated folios, the first of which was devoted to the anatomy of the nervous system and connective tissue, the second and third to anthropology, the fourth and fifth to the brain of man and monkeys and the sixth to the organ of hearing. His name has been given to parallel brown lines crossing the enamel-prisms of the teeth seen on cutting the enamel, and, with that of Key, to two foramina in the brain. He was awarded many prizes for his work, including the Montyon Prize of the Institut de France. He died on July 21, 1919.

DR. WILLIAM BRADLEY, lecturer in tinctorial chemistry and dyestuffs in the Manchester College of Technology, has joined the scientific staff of the British Drug Houses Ltd. His research work in organic chemistry includes the disclosure of the mechanism of the so-called Nierenstein reaction, the development of the theory of aromatic substitution by anionoid reagents, and the advancement of the chemistry of the anthocyanidins and of benzanthrone.

The Saqqara Graph: its Geometrical and Architectural Significance

THE Saqqara graph, drawn on an ostrakon, has been described by Gunn[1], and discussed by Clarke and Engelbach[2]. Jarrett Bell[3] has suggested that ordinates of the dimensions written on the ostrakon can be obtained by drawing, in a quadrant of a circle of radius 9 cubits 1 finger (253 fingers), a line parallel to the base and 155 fingers from it, and on this line erecting ordinates spaced 40 fingers apart. (The length of this base line is thus 200 fingers.) His results are tabulated thus:

Height of ordinate of arc of circle as calculated	98	94·8	85	67·7	41	0
Height given on ostrakon	98	95	84	68	41	0

(The '84', differing from 85, is explained as probably due to careless measuring, or writing 3 cubits for 3 cubits 1 finger.)

These results seem to confirm Jarrett Bell's suggestion. I found some dissatisfaction, however, in the fact that the figures 155, 253 and 200, though connected, of course, by the Pythagorean relation $(253)^2 - (155)^2 = (200)^2$ approximately, have no *simple* relation to each other such as one might expect an Egyptian to have used. I therefore tried a base line the length of which was exactly four fifths of the radius.

In Fig. 1, OR, the radius, is 5 units, and XY, the base line, is 4. By Pythagoras' Theorem, $OX = 3$, so $aX = 2$. The lengths of the other ordinates b, c, d, e, which are 0·8 units apart, are given by y in:

$$(y+3)^2 = 5^2 - 0{\cdot}8^2;\ 5^2 - 1{\cdot}6^2;\ 5^2 - 2{\cdot}4^2;\ 5^2 - 3{\cdot}2^2.$$
$$= 24{\cdot}36;\ 22{\cdot}44;\ 19{\cdot}24;\ 14{\cdot}76.$$
$$y+3 = 4{\cdot}936;\ 4{\cdot}737;\ 4{\cdot}386;\ 3{\cdot}842.$$

The ordinates, a, b, c, d, e, are therefore 2; 1·936; 1·737; 1·386; 0·842.

On multiplying these by 49, to change 2 to the required 98, these figures become: 98; 94·9; 85·1; 67·9; 41·3.

These results are as close to the ostrakon measurements as are those of Jarrett Bell, and, in view of the simplicity and significance of the geometry of Fig. 1, it would seem that the ostrakon measurements were derived from a similar figure. To obtain the lengths 98, 95, 85, 68, 41, as direct measurements from a circle, the radius, OR, should be 245, that is, 5×49, OX 147 and XY 196. A modern mathematician might expect the Egyptian to have used round numbers like 250, 150, 200. These numbers, indeed, are suggested by Jarrett Bell's 253, 155, 200, and, being in the proportion 5 : 3 : 4, satisfy the geometry of Fig. 1. The Egyptian, however, might find occult significance in 245, 147, 196, since they are the respective products of 5, 3, 4 by "seven times seven". On the other hand, these numbers may have come out of the circumstances for which the graph was drawn on the ostrakon. The curve of the graph apparently gives the shape of a saddleback construction near which the ostrakon was found (Clarke and Engelbach).

It is instructive to consider the possible use of the circle of 5-unit radius, that is, Fig. 1, in connexion with the construction of a required arch. The architect would first fix the height of the arch, h, and the length of its base, $2b$. He would then draw the system of squares on which he was accustomed to work, making the distance between successive parallel lines equal to $\frac{1}{2}h$ (see aP in Fig. 1). He would then mark a and X, two squares apart, with P midway between, and O three squares from X; also Y, four squares from X, and the symmetrical point Q the co-ordinates of which are (3, 4). He would thus have found four points on the quadrant, which could then be drawn, ordinates being added as required. I see no reason why the ordinates should be limited to five in number. In any event their lengths would be read off, and ordinates of this length erected at equal intervals along a line of length b.

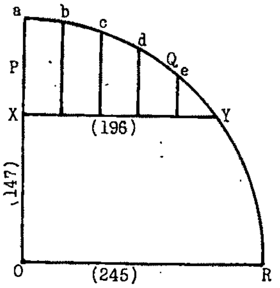

Fig. 1.

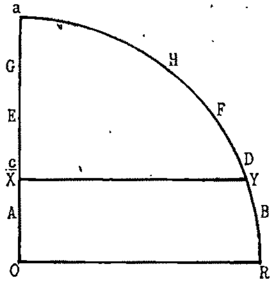

Fig. 2.

This method could be adapted to suit any position of the base line XY. Thus (Fig. 2), h being known, aX $(= h)$ would be drawn and O arbitrarily fixed. aO would then be divided into five equal parts, and the system of squares drawn. F and H would be found by their co-ordinates (4, 3) and (3, 4), and the figure completed as before. The nearer XY is to OR the more rounded will be the arch at its ends, and the more curvilinear generally.

Capart[4] points out that the Egyptian artist used his system of squares to provide a canon for the drawing of human figures. Bearing this in mind, one can imagine a canon of arch construction in which the position of the base line XY would be limited to five possibilities, namely, OR, AB, CD, EF, GH (Fig. 2), which lie on consecutive lines of the system of squares. At a later period this scale of base lines might be abandoned, as the historic diatonic scale has been abandoned by the atonalists of to-day, in favour of a freer canon under which any line parallel to OR served as base line.

As regards the geometrical significance of the Saqqara graph, it is shown that the construction of the circle of 5-unit radius is facilitated by using the fact that points with co-ordinates (3, 4) and (4, 3) lie on its circumference. Since the Egyptian architect constantly used a squared surface, it seems reasonable to suppose that he knew this fact, which depends on the rectangular property of the triangle of sides 3, 4 and 5 units. The Saqqara graph is geometrically important because it furnishes definite evidence of this knowledge, if my suggestion that it was evolved from a base-line of four fifths of the radius of a circle is accepted. Thus we arrive at the interesting conclusion that the geometrical basis of the Saqqara graph, and possibly of a canon of arch construction, is the right-angled triangle of sides 3, 4 and 5 units.

This triangle was therefore probably known to the Egyptians as early as the fifth millennium B.C., as the ostrakon is ascribed to the Third Dynasty.

Function of the Kidney in Dehydration

ONE of the minor consequences of total war is the resurgence of classical physiological problems, such as the effects of hæmorrhage and of dehydration. Although pure dehydration, in the sense of a deficiency of water but not of salt, is rarely met with clinically, it is precisely this disturbance which presents itself in desert warfare, and in lifeboats or on rafts. One aspect of dehydration which has received much less attention than it deserves is the function of the kidney. Very little urine is formed, and it might have been anticipated that there would have been interesting changes in its composition, and possibly in its mode of secretion. There was the possibility, for example, that a shortage of water in the organism might lead to a diminished blood flow to the kidney, or a diminished glomerular filtration rate.

The urea, inulin and diodone clearances have been letermined in four men who had abstained from all water for three or four days, while taking a dry diet upplying adequate protein, calories and salt. They had lost 4 per cent to 7·2 per cent of their body weights. The results are shown in the accompanying table.

Subject		Volume of urine (c.c./min.)	Inulin clearance (c.c./min.)	Diodone clearance (c.c./min.)	Urea clearance (c.c./min.)
A	Normal	5·70	124	570	66
	Dehydrated	0·66	96	550	20
B	Normal	1·70	119	473	52
	Dehydrated	0·64	99	508	38
C	Normal	1·10	121	470	66
	Dehydrated	0·52	107	615	35
D	Normal	0·95	130	670	77
	Dehydrated	0·55	128	765	39

As was to be expected, small volumes of urine ere passed during dehydration, and the urea clearnces were correspondingly reduced. Three of the en showed a fall of about 20 c.c. per min. in the ulin clearance; but to appreciate this fall in omerular filtration rate in its proper perspective, ne must compare it with the much greater reductions inulin clearance which have been found in diabetic ma[1], alkalosis[2], hæmatemesis[3] and in the dehydraon of young infants with gastroenteritis[4]. The odone clearance, which may be taken to measure nal plasma flow, is much more variable, even in rmal subjects, than the inulin clearance; but our ures did not give any evidence of a reduction in e amount of blood flowing through the kidney. In harmony with this, it has been observed by Nadal *et al.*[5], and confirmed in the present investigations, that there is no hæmo-concentration in dehydration of this degree, so that there can be little alteration in blood volume.

One must therefore consider the kidneys of a dehydrated adult as essentially normal with regard to the amount of blood supplied to them, and in the amount of glomerular filtrate formed. Consequently, the very striking changes in the volume and constitution of the final urine must be determined by tubular activity, stimulated no doubt by pituitary, suprarenal and possibly other hormones.

Use of Desiccated Chick Embryo in Tissue Culture Technique

THE successful use of desiccated 9–11-day chick embryo as a source of growth-promoting factor was reported in 1940 (Peacock and Shukoff). Since then, repeated tests have been made with desiccates stored for periods up to 2½ years at 4° C. All the samples tested were equally effective and retained their growth-promoting potency and their capacity to coagulate plasma. Apart from the advantages of essential economy in war-time, the use of dried embryo greatly simplifies the technique of tissue culture and helps to standardize results, as it tends to eliminate any individual differences between embryos, and one batch of desiccate can be used for a long series of experiments. Freezing at 0° C. does not appear to affect the desiccates, but storage in a refrigerator at 4° C. has proved quite satisfactory.

Potassium, Fermentation and the Cell Membrane

IN a letter in NATURE[1] and subsequent communication to the *Journal of Physiology*[2] there was described, with experimental verification, the principles controlling the accumulation of potassium in isolated muscle. This accumulation could occur to a considerable extent without volume change, and the theoretical position established led naturally to an explanation of the potassium content of the original muscle. Further aspects were considered in later communications[3, 5], Prof. F. G. Donnan also contributing[6, 7].

Viewed in the light of this theoretical development, Pulver and Verzar's description of experiments showing the accumulation of potassium in the initial stage of fermentation in yeast, and its subsequent release[8], is of much interest, as also the recent account of a similar occurrence in bacteria (*E. coli*) by Leibowitz and Kupermintz[9]. These experiments are in fact beautiful illustrations of the principles of potassium accumulation[1,2], and the explanation concerning the potassium exchanges is as follows. The yeast membrane, for example, is permeable to potassium and cations of the same or lesser diameter, but is impermeable to sodium or ions of greater diameter (the sodium ion, as is well known, being larger than the potassium ion from the greater number of associated water molecules). The membrane is permeable at the same time to phosphate but not to ions of greater diameter such as the phosphate esters of hexose or adenosine—and this type of electrolyte permeability need only be postulated for the active or growing cell. When glucose enters from without, it is esterified and the effective product of the concentrations of the potassium and phosphate ions falls within. Phosphate enters therefore and can only do so with potassium, more phosphate is esterified, and the process goes on as long as the esters accumulate and hold potassium in equivalent relation. Meanwhile part of the glucose is synthesized to glycogen, so that more glucose than potassium molecules will have entered the cells. As the fermentation proceeds, the accumulated esters will be again broken down, and ultimately to carbon dioxide, alcohol and phosphate, so that the effective product of potassium and free phosphate ion concentrations becomes greater than at the outset, and potassium and phosphate will leave the cells.

It will appear from this description that an ion as small or smaller than potassium should serve as well, provided it is likewise comparatively unreactive chemically with respect to the mechanisms involved. It has been shown[5] that all the potassium ion can be taken out of yeast under certain conditions and replaced with the ammonium ion, and that such yeast will ferment glucose quite readily, and the cells multiply.

The membrane permeability described above, applying to yeast, and to muscle and other tissues of vertebrates, would seem to be of a general kind, though it may be occasionally altered in cells of a very specialized function. It is, in short, and with respect to electrolytes, the normal or standard pore permeability of the cell membrane, and why it should be so has been briefly considered[3]. Distinct from this pore permeability is what may be termed the wall permeability concerning the passage of substances as solutes through the substance of the membrane. Such substances include the lipoid soluble group and possibly ions like magnesium which may enter into organic combination with cell membrane constituents.

Interatomic Distances in Carbon

IN a recent paper, B. E. Warren[1] has developed a mathematical treatment of the diffraction of X-rays from random layer-lattices and has derived the Laue[2] expression for the asymmetrical shape of a cross-grating spectrum line which such a lattice produces. He has also shown that when the dimensions of the cross-lattice are small, they can be computed from the formula

$$\beta = \frac{1\cdot 84\,\lambda}{\varepsilon\cos\theta}, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where β is the line broadening in radians, λ the wavelength of X-rays, ε the dimension of the cross-lattice, and θ the Bragg angle. This means that the particle size so calculated is approximately *double* the size obtained from the well-known Scherrer equation

$$\beta = \frac{c\lambda}{\varepsilon\cos\theta}, \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where c has a value of the order of unity[3].

A further consequence of the Warren theory is that the peaks of the asymmetrical cross-grating spectra are displaced from their positions in the direction of increasing θ by an amount which depends upon the crystal size. The increase in sin θ is given by $\Delta(\sin\theta) = 0\cdot 16\,\lambda/\varepsilon$. Thus the lattice spacing d calculated from the Bragg equation $2d\sin\theta = n\lambda$ would be in error by an amount

$$\frac{\Delta d}{d} = -\frac{\Delta(\sin\theta)}{\sin\theta} = -\frac{0\cdot 16\,\lambda}{\varepsilon\sin\theta}, \quad . \quad . \quad . \quad (3$$

if the two-dimensional nature of the lattice producin the spectrum line were not appreciated.

A direct test of the validity of equations (1) an (3) can be made by applying them to the data alread available on carbon. U. Hofmann and D. Wilm H. E. Blayden, H. L. Riley and A. Taylor[5] and T Schoon[6] have found that as the *a*-dimension of carbo decreases, there is an apparent *decrease* in the parameter, which would mean that the distance o approach of the carbon atoms in the net planes be comes appreciably smaller by an amount far greate than the normal experimental errors in the measur ments of the diffuse Debye-Scherrer halos. In vie of the extremely strong linkage between the carbo atoms in the net planes, such a large decrease in th interatomic distances is very difficult to understan

This has led me to review these data in the light the Warren formulæ. All the crystallite sizes obtaine by the workers mentioned above have been obtaine by using equation 2 with $c \approx 1$. Now if, in co formity with equation 1, we compute the true lay lattice dimensions ε, which are almost double t *a*-dimensions obtained by the various workers me tioned above, and substitute these new values equation 3, we obtain a series of corrections whi can be applied to the corresponding C–C distanc The results averaged out for a large number of c bons are illustrated in the accompanying gra Curve *a* indicates the earlier values of the C distances plotted against the *a*-dimension obtain on the basis of equation 2, which approach asymptot ally the value of the C–C distance in macrocrystalli graphite. Curve *b* shows the same C–C distan plotted against values of the *a*-dimension obtain with the new equation 1. On applying the correcti to curve *b* on the basis of equation 3, we get almost *constant value* of the interatomic distance result which could not have been obtained from original crystallite dimensions given in curve *a*. T *c*-dimensions of carbon, however, must still be computed from equation 2, since the 000*l* reflexions are not cross-grating spectra.

These results are so reasonable that there can be little doubt that they afford a direct verification of the validity of equations 1 and 3. I have long felt that the existing values of the *a*-dimensions for 'amorphous' carbons calculated from Debye-Scherrer photographs have been much too small. Earlier results seem to indicate that the first stages in the grain-growth of carbon could be associated with rod-like crystallites, whereas plate-like crystallites seem much more reasonable on the basis of our existing knowledge of the grain-growth of crystals. The new cross-lattice dimension equation is in conformity with these latter ideas.

Similar cross-lattice problems may also arise in the study of alloys, where phases precipitate out of solid solution in the form of fine lamellæ, or where two allotropic modifications of the same element, hexagonal close-packed and cubic face-centred cobalt, for example, form successive layers of submicroscopic thickness by gliding along planes perpendicular to a common trigonal axis.

Buddleias on a Bombed Site

The appearance of considerable numbers of plants of *Buddleia variabilis* on a bombed site in Kensington, was recorded in Nature[1], is not an isolated case. During a recent study of the flora of the site of three bombed houses in Kew, numerous Buddleia plants were found. The houses were bombed in the autumn of 1940 and the sites cleared in the following spring. In addition to many weeds characteristic of waste ground there are at least sixty Buddleias. Some of these are 5–6 ft. in height and have bloomed freely; others are smaller plants but many have also flowered. There are no Buddleias in the gardens of these three houses, and I have not identified the parent plant, but Buddleias are present in the neighbourhood though at some distance. Buddleia seeds are extremely small and have certainly reached the site by being wind-blown. The success of the plants is probably largely due to their long, sturdy tap-roots, which have been able to penetrate the hard down-trodden surface material and to reach the sandy subsoil.

Mating Call-note of Moths

A few days ago, a female ground lackey (*Malacosoma castrensis*) was disturbed in daylight from its shelter in canvas in a loggia. It alighted on a table and commenced to vibrate its wings in a very small radial arc to attract the male. Bending low over the moth, I was astonished to hear a powerful, low-toned hum like that of a distant single-engined fighter. As the latter are not uncommon here, the observations were repeated to make sure the ear was not deceived.

Formerly, it has been suggested that the female emitted waves of a length too short to be perceived aurally. I had earlier discovered that this quivering of the wings could be induced by gently stroking the dorsal hairs of the Silver *Y* (*Plusia Gamma*), but on that occasion no aural observation was taken.

Nova Cygni (1942)

On September 18 the Norman Lockyer Observatory, Sidmouth, was informed of the discovery by Zwicky of a nova in Cygnus at R. A. 20h. 56m., Dec. + 35·7°, mag. 8. Cloudy sky prevented an observation before September 22. Since this date the region has been photographed seven times on four nights. Clouds prevented more work being done and bright moonlight restricted the exposure time. Only the night of October 1 was clear and steady, and a photovisual exposure of 2h. was obtained.

Photographic and photovisual magnitudes were determined with the help of about twenty standard stars (taken from the H.D. catalogue) and are listed in the following table:

Date	Exp.	*mp*	*mpv*
1942 Sept. 22	7m. 30s.	10·14(±0·18)	10·03(±0·17)
,, 23	20m.	$12 > N > 11{\cdot}5$	$12 > N > 11{\cdot}5$
,, 24	20m.	>12	>12
Oct. 1	2h.		$15{\cdot}5 > N > 14{\cdot}5$

While the exposures of September 22 gave a well-defined star image in 7·5 min., the magnitude decrease was so rapid that no later exposure yielded a measurable image despite increased exposure time: on the plates of September 23 the star image could be easily recognized but not measured; on the plates of September 24 no star image appeared at all, the faintest star magnitude on the plate being about 12 on both dates; the plate of October 1 yielded a recognizable but not measurable star image, the limiting magnitude being 15·5.

There was thus magnitude loss of about 5m. in nine days. So rapid a fading, corresponding to a drop of intensity to one hundredth, occurs very rarely with novæ. A similar steep fall is known only with three novæ: Coronæ (1866)[1], Aurigæ (1892)[2] and Herculis (1934)[3]; the decreases were 4·2m. in eight days, 7·4m. in twenty-three days and 5m. in ten days, respectively. The average magnitude loss (0·5m. per day) is about the same in all cases, except Nova Aurigæ (0·3m.), but the sudden fall of about 1·5m. within twenty-four hours—between September 22 and 23—is equalled only by Nova Herculis between April 3 and 4 (6·2m. to 7·6m.). Thus Nova Cygni seems to resemble Nova Herculis, at least in this part of the light curve.

Note added in proof: On October 11 the Observatory succeeded in getting another photograph of 2h. 15m. exposure time on which the star image was only just visible, and the magnitude must therefore have been equal to or less than 16m.

Functions of the Research Associations

It is difficult to draw valid conclusions from any generalization about "industrial research". It covers a wide field of subjects and an equally wide field of quality. Depending upon the particular industry and the type and size of firm engaged in it, "industrial research" ranges from relatively minor constructional or similar developments right through to real research upon scientific fundamentals. The extent to which the latter is possible by individual firms depends so much upon the extent of the permissible expenditure that the work of the research associations tends also to cover an equally wide range.

Without doubt cases exist where criticism can be levelled at the lack of intimate knowledge of the work of the industry possessed by the staffs of the research associations. It is to meet such deficiencies that I support the suggestion of greater interchange between their staffs and those of the industrial laboratories. Such exchanges would, in my opinion, help both parties; and I would not restrict such interchange to any except the director and his immediate assistants.

Dr. Toy[1] is certainly correct in his statements concerning the essential nature of confidence in the association's staff, but I feel that these staff interchanges should only help to increase such confidence by broadening the knowledge each of the others. Among many industrialists this complete confidence does not exist, particularly when it is known that the association's staff have had no personal practical contacts with the work of the industry. In these instances, the tendency is undoubtedly to confine the association's work to generalities—such as can be guided by a committee.

I do not overlook the very many original and often fundamental researches that have been completed by the research associations; but I am sure that a more free interchange of personnel would aid such work, and would help towards Sir Lawrence Bragg's aim of discovering "the best way of applying our great natural scientific ability to the strengthening of our industrial position".

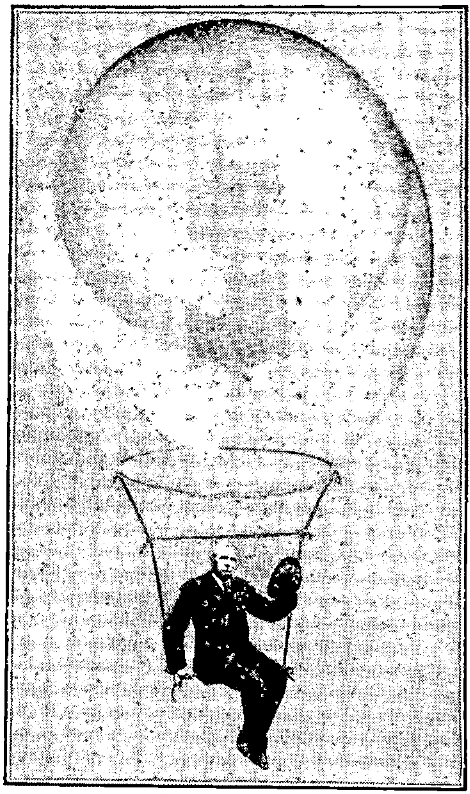
A Flight of Pure Imagination

It is possible that the enclosed photograph and lines might not be out of place in Nature as a sequel to Sir Richard Paget's verses of June 15, 1935. So far as I can remember, I took the photograph some time after the year 1912 when my paper on rotating films appeared (*Proc. Roy. Soc.*, **87**) and the Rainbow Cup became a popular scientific toy. I then intended to get out a third edition of my book on "Soap Bubbles" with the Rainbow Cup as the chief addition, and the idea of the fake photograph occurred to me as being a permissible diversion. Stumbling upon this at the present time, with the Paget verses fresh in memory, the seven lines with the photograph of which three are quoted, flashed across my mind and seemed appropriate for publication. This must be my apology.



"Why does Sir C. V. Boys elect
To do the things we least expect?"
Sir Richard gave the explanation*.
But how? Well, here's an illustration—
"A photograph which cannot lie"
Shows clearly that he does it by
A flight of pure imagination.

I am indebted to Messrs. Kodak Ltd. for the prin from which the figure is taken, in which they have eliminated a blemish in my original negative.

C. V. Boys.

ENGLISH SOCIAL STRATIFICATION

SOCIAL stratification exists in most societies, yet upon the English it exerts a powerful, subtle and complex influence, to a much greater extent than in younger culture-patterns. Strangely, however, the subject has attracted very little attention from psychologists. Psychologists ought to regard social stratification as a problem to be studied as objectively as a geologist studies the layers in a cliff face. The practical issues are of importance for the welfare of the future*.

Social stratification, however, is not the result of inevitable forces. Already since the War we have seen many changes, changes which are much more difficult to study in a large town than in a village. One classification distinguishes between those with opportunities and those without; in some parts of the country even the probability of living is less than in other more favoured localities, while positions of power and responsibility tend to go to persons chosen from an arbitrarily restricted group. If the diplomatic and civil services are to be made effectively democratic a definite study ought to be made of the requirements, and of the arguments for and against drawing from a narrow group.

Another classification is the social one based mainly on titles, money, ownership of land, education, contrasted with the stigma attached to the performance of manual work. This two-class division of English society means that public life is administered too requently by people who know little at first hand about the life of the general public. Social differences are shown by choice of words and phrases, speech-melody, manners and games, and, to a certain extent, eligion. The solution of many problems in social psychology needs more knowledge of the sentiments and ideals which characterize different social strata; so it is necessary to study the more and the less desirable social phenomena, to find out how, when he causes are not economic, they have arisen. It would be a pity if the lessening of privilege led to a decreasing tolerance of individual differences.

DETERMINATION OF EQUILIBRIUM DIAGRAMS BY X-RAY METHODS

A DISCUSSION on the determination of equilibrium diagrams by X-ray methods arranged by the Institute of Physics was held at the Royal nstitution, London, on September 22. The chairman, Sir Lawrence Bragg, pointed out that the meeting was largely due to Dr. W. Hume-Rothery's initiative, and that it might be regarded as a continuation of the Institute's conference on X-ray technique held t Cambridge last Easter.

The opening talk was by Prof. E. A. Owen, Bangor, who was one of the first to apply X-ray methods to the study of equilibrium diagrams in an exact way, is subject being "The Determination of Phase Boundaries in Equilibrium Diagrams by X-Ray Methods". The accurate determination of lattice parameters was begun at the National Physical Laboratory, the initial publication being that of Preston and Gayler on the "Age Hardening of opper-Aluminium", who used a focusing camera. This method has been largely used by Prof. Owen for determining phase boundaries. One of his first publications was "A Determination of the Limit of the α-Solid Solution in the Copper-Zinc System". The results agreed well with those found by the standard metallurgical methods, but copper-cadmium caused more trouble on account of the volatilization of the cadmium. Zinc alloys could also be made by heating a mixture of the powdered metals to the melting point of zinc. Then alloys were investigated in a high-temperature camera, the aluminium-zinc system being studied by this means. Later work by Gayler has confirmed the accuracy of this research, satisfactory results being obtained up to the melting point of zinc. The accuracy of the work depends on the composition and on the lattice parameter. The more rapidly the parameter changes with composition the better the results are likely to be. It is more difficult if the boundary changes very rapidly with increasing temperature, as in the copper-indium system, and accurate temperature control is vital.

In order to make alloys of more reliable composition, Prof. Owen has devised a shaking furnace. The materials are placed in small silica tubes which may be lined with graphite. After shaking for a quarter of an hour or longer, the alloy may be quenched or slowly cooled to obtain very small ingots down to half a gram in weight. Specimens selected from different parts of the ingots were sent away for analysis. There is usually agreement to 0·1 per cent with the intended compositions. The powders from these specimens are sieved before use and heat-treated in an evacuated silica or 'Pyrex' tube. The work has been checked up by a satisfactory comparison of the results from alloys made up by fusion and interdiffusing. Identical parameter measurements have been obtained from powders and from solid specimens.

Extremely reliable results have been obtained even with the silver-arsenic system, no errors due to volatilization being detectable. A very important point is the effectiveness of quenching. A special furnace has been devised by means of which specimens may be quenched in less than two seconds.

The α boundary of the copper-tin system has been determined with an accuracy of 0·1 per cent. Similar results were found for the copper-aluminium system, but there is more difficulty with the silver-aluminium system because the β-phase is not retained, the possible error being 0·4 atomic per cent.

Dr. W. Hume-Rothery spoke on the application of X-ray methods to the determination of phase boundaries in metallurgical equilibrium diagrams. Two types of investigation are valuable: either the determination of a rough equilibrium diagram or the determination of an accurate diagram. For the rough survey it is preferable to use X-rays in conjunction with the older methods, the former for the lower, the latter for the higher, temperatures. There is, however, a possibility that the filings will not behave in the same way as the lumps, particular precautions being required to deal with two-phase alloys, where the powders may give misleading results unless each particle contains both phases in the same proportions.

For accurate work the liquidus and solidus are best determined by the older methods, but for investigating transformations in the solid state the high-temperature camera supersedes thermal analysis provided that the composition of the filings is accurately known. Moreover, the X-ray method is particularly useful for the identification of phases in ternary and other complicated systems.

The older methods are more sensitive for the determination of the precise limits of the phase boundaries, yielding an accuracy of one part in a thousand for the microscope. Prof. Owen's results are invaluable for comparing the X-ray with the microscopic technique. The α-phase boundaries lead to satisfactory agreement, but in the case of the two β-phases there are wide divergencies at the higher temperatures. This may be ascribed to unavoidable decomposition of the filings during quenching, and it is therefore advisable that specimens should be examined by the microscope to test whether they are suitable for the application of the X-ray method.

Work done at Oxford includes an examination of the copper-gallium diagram by X-rays. The β-phase was examined in the high-temperature camera and in the form of quenched filings. At the high temperatures the structure is body-centred cubic, but during quenching it is transformed to hexagonal close-packed. Another difficulty in the use of the X-ray method is that the relation between the lattice spacing and composition within a phase is not necessarily a smooth one. A notable example is the iron-aluminium system; also many systems containing magnesium recently investigated by Dr. Rayner at Oxford. In conclusion, it is now recognized that there are so many pitfalls in the use of X-rays for the exact location of phase boundaries in equilibrium diagrams that help is needed from other methods.

Dr. A. J. Bradley spoke on the examination of heat-treated alloys by X-rays and the microscope. Alloys must be made up from extremely pure ingredients, say 99·95 atomic per cent. The discordant results obtained from the aluminium-manganese system can probably be ascribed to the gross impurities formerly found even in the best manganese available. Errors in the initial composition are not always put right by chemical analysis, for when the amount to be analysed exceeds 50 per cent of the alloy, there may be difficulties in reaching the desired standard of accuracy. Lattice spacing measurements are then a valuable check on chemical analysis.

Before X-ray examination alloys must be lump- and powder annealed. The former gives uniformity, the latter impresses a definite structure on the specimen. Lump-annealing treatment is only effective if carried out just below the final freezing point or solidus temperature. For example, $NiAl_3$, when cooled from the melt, is found to be contaminated with Ni_2Al_3 and aluminium. Lump annealing, if carried out at the right temperature, produces pure $NiAl_3$. Powder annealing is necessary to give good X-ray photographs, as the act of filing or grinding may be enough to change the crystal structure of the original lump; but, on the whole, the annealed powder should correspond more exactly to true equilibrium conditions.

The microscope shows the difference between a single-phase alloy and one containing two or more phases, but only the X-ray method can show with certainty which phase is present. Thus in theory the X-ray method is the ideal means for the investigation of alloy equilibrium diagrams; but at present the microscopic technique, being the more fully developed, is the more reliable. This is especially true at high temperatures, as the high-temperature X-ray camera is still in its infancy.

Heat treatments must be greatly lengthened as the temperature is lowered, but structures which a readily shown up by the X-ray powder method afte a few days heat treatment may be invisible unde the microscope even when the alloy has been heate for weeks, owing to the fine nature of the precipitat When the structure is decomposed during quenchin as in the change from austenite to martensite, combination of the two methods is essential.

Dr. L. M. V. Gayler gave a brief summary of th classical methods used by metallurgists for dete mining equilibrium diagrams. Chemical analysis an essential foundation upon which all physic measurements should be based. The use of X-ra is subject to certain limitations. The liquidus an solidus of a system must first be established by th older methods. There is still much to learn abo the nature of the freezing point. Why do some phas such as CuAl and $CuAl_2$ separate by peritectic r actions, whereas Cu_3Al comes directly from t melt? X-rays have been very little used on suc problems.

Small amounts of fine-grained precipitate, thoug identified by the microscope, may be insufficient t register on the X-ray film; but X-rays are of co siderable use in identifying unknown phases ternary systems, even if they sometimes overlook th presence of a phase which has been seen micr scopically. This is not improbable when there a two phases present with the same structure, and suc a case occurs in the tin-silver-mercury syste Where there are transformations in the solid, bot metallurgical and X-ray methods are necessary.

When transformations cannot be suppressed b quenching, high-temperature X-ray work is e tremely valuable. It is essential to use X-rays f the examination of superlattices, but it see doubtful whether they should be inserted on a equilibrium diagram. Time may be saved by t X-ray analysis of powders. Cold work, recrysta lization and grain growth are best studied by X-ray Solid solubility limits are readily determined them, but the process of precipitation should also studied by other means. The use of both X-ra and the microscope is like changing the degree magnification, and both are essential.

Sir Lawrence Bragg then discussed the value equilibrium diagrams, and pointed out that t essential fact is not the exact boundary, as th depends largely on accidents in the previous he treatment, but rather what possible phases m exist. Neither is the equilibrium diagram direct used in industry, as all industrial materials are o of equilibrium. One possible criticism of the X-r powder method is that industry is more interest in metals in the lump form. Their gas content important.

Dr. D. Stockdale emphasized the importance purity, equilibrium, analysis and the method examination. More than one method should be use especially to check up changes of phase duri quenching. For example, in the aluminium-copp system, the microscope gives more reliable resul than the X-ray method for the β-phase, but t silver-copper system gives identical results by eith method. Where there are discrepancies it will oft be found that in the earlier work pure metals we not available, or insufficient precautions were take

Mr. D. A. Oliver stated that extreme accuracy scientifically important but that the practical m would like to have a collated system of diagra revised every five years. While it is desirable to u a variety of methods, X-ray work has yielded brilliant results. Dr. H. Lipson gave an example in direct conflict with the theory of phase equilibrium, that of the metal cobalt. The purity of the metal was 99·99 per cent, and yet it was not possible to find a definite transition point. On cooling, the hexagonal form begins to appear just above 300° C. and the amount increases down to room temperature. On reheating, it only changes back to the face-centred cubic form above 400° C.

Mr. G. D. Preston pointed out that X-rays can give additional information not available by the microscope. The mechanism of phase changes is most important. Dr. G. V. Rayner supported accurate work in order to supply reliable data to the theorists. He agreed that the X-ray method would often give results just as accurate as the microscopic, but it was no more speedy in operation.

Dr. W. Wrazej described the use of X-rays in the investigation of an iron alloy which showed two distinct groups of crystals on microscopic examination. The problem was whether these belonged to different phases or whether they were merely differently oriented crystals. The back-reflexion method proved that the latter was the true explanation.

Dr. A. H. Jay stated that he had just designed an X-ray camera to work up to 1,500° C. In determining phase boundaries by the lattice spacing method, difficulties were caused by irregularities as in the iron-nickel system. He expressed some scepticism about the value of extremely pure materials; results do not always come up to expectations.

Dr. H. O'Neill, though very interested in phase diagrams, does not consider that extreme accuracy is of vital importance for industrial work. If alloys are examined in the lump form, the polished surface layer gives broadened lines. If this is removed by etching, there is a selective solution and the X-ray results are unreliable. Gas may upset the equilibrium of alloys. It would be interesting to follow the tempering process of steel at 400°–300° C. by means of X-rays. Dr. J. L. Haughton directed the attention of the audience to the value of other physical measurements, such as electrical conductivity and dilatation.

Dr. L. Frommer finds it necessary to investigate his specimens in the form of lumps, because he is trying to follow the industrial process of age-hardening in a complex aluminium alloy. The difficulty is to obtain a useful surface. For this purpose he uses diamond turning and faces up the surface with the diamond. This prevents the surface layer from being distorted as with polishing. Dr. A. H. Jay has used a special method for getting X-ray photographs without powdering. A high narrow slit is used, the specimen being rotated to give continuous lines.

Dr. W. Hume-Rothery then commented on a point raised by Prof. Owen, who showed that the X-ray method follows the solubility curve better than the microscope at lower temperatures, and explained that it only needs more care to improve the microscopic results without waste of time. In answer to a request from Dr. Hume-Rothery for an explanation of intensity methods for determining phase diagrams by X-rays, Dr. A. J. Bradley remarked that the method has been mainly used for the determination of three-phase triangles in ternary systems. It needs three alloys in each triangle to give the approximate compositions of the corners from the relative proportions of the phases present in each alloy. More exact values can be obtained by making a new alloy near each corner. Much less than 1 per cent of the face-centred cubic or body-centred cubic phases can be detected, but it is sometimes difficult to detect the presence of phases with more complex structures. A very large camera would be needed if the structure was of low symmetry. Time is saved when the system contains many triangles.

Mr. C. Wainwright stressed the importance of expert chemical analysis. Mr. N. J. Petch pointed out that there is a vital difference in the behaviour of lumps and powder from low-alloy steels. Often when the lump remains austenitic, quenched filings may contain a great deal of martensite. Dr. A. H. Jay, in agreement with a previous speaker, recommended the electrolytic method of preparing surfaces instead of acid etching, which is not reliable.

Dr. H. Lipson would like to study the liquid state by means of X-rays, but considers that the microscopic method should be left to the metallurgists, while Dr. M. L. V. Gayler pleaded for co-operation between physicists and metallurgists. Emphasis was placed on the difference in behaviour between pure and commercial metals. Prof. E. A. Owen was also in favour of co-operation, and strongly supported the focusing camera.

Dr. W. A. Alexander pointed out some discrepancies between X-ray and microscope results on the nickel-aluminium system. In the copper-nickel-aluminium system there is a decrease in solid solubility as the alloy cools, which is important from the point of view of the hardening of copper-rich alloys. There is supersaturation at low temperatures. Dr. A. J. Bradley suggested three stages in precipitation at low temperatures: the first affects the physical properties, the second the X-ray results and the third the microscope results.

Mr. F. A. Fox urged that the X-ray worker should use the microscope, and Dr. L. Frommer stated that quenched lumps differ from the surface to the interior.

ELECTRICAL ENGINEERS AND THE POST-WAR PERIOD

IN his inaugural address on October 1 to the Institution of Electrical Engineers, Prof. C. L. Fortescue first referred to two aspects of the political and economic conditions likely to prevail in Great Britain after the War. First, a great effort will be made to improve the living and working conditions of the less highly paid members of the community; and secondly, Great Britain will for a long time import a large proportion of essential food supplies and a considerable quantity of the raw materials required for industries.

In discussing the export and import tendencies and in proposing a course of action to redress the balance, Prof. Fortescue considers that one of the first problems to be coped with in the post-war period is the conservation of coal and its more efficient use. In this connexion reference is made to the Weir Committee's report of 1931 on main-line electrification and to the Moore-Brabazon Committee's report of 1933 on the Severn barrage scheme, the provisions of which would save 9–10 million tons of coal a year in the one case and about 1½ million tons in the other. The Caledonian power and the Grampian (Glen Affric) power schemes are also mentioned.

In the domestic sphere an improvement in the efficiency of heating apparatus might play a greater part in the conservation of coal than would the development of the rather scanty sources of available water-power. The possibility of using the energy of the condensate from power stations offers good prospects when planned in combination with intensive horticulture on a large scale and industries requiring considerable quantities of process steam.

Prof. Fortescue outlined the facilities and training which in his view should be made available to young men entering upon engineering careers in the post-war years. The school-leaving age will probably be raised to 15 or 16, and four or five years will be needed after that for training in the sciences and for workshop instruction. A further two or three years should be devoted to subject-matter chosen from engineering practice, mathematics applied to engineering problems, industrial economics, works administration or industrial psychology. The student's final award would depend on the work done during the first four or five years and on the presentation of a satisfactory thesis covering the work of the later years; at the conclusion of this, the student should be ready to take his place in productive industry.

Prof. Fortescue makes a plea for the thorough investigation by engineers of the relative advantages of road and rail transport in Great Britain and also in such other spheres as the public health services and agriculture. The necessary researches would need to be conducted on a national scale, possibly by a national research institution or perhaps an extended Department of Scientific and Industrial Research.

Then there will be the urgent and difficult problem of reabsorbing men into industry from the Armed Forces without dislocating the lives of those who have remained in industry. Tentatively it is suggested that all the younger men in industry be gradually drafted into the Forces, after the War, for two or three years of military duty, their places being taken by men of suitable qualifications now in the Forces. By the time the young men from industry have completed these military duties, industry should be in a position gradually to re-absorb them.

Another problem of the immediate post-war period is that of ensuring that all large schemes of industrial replanning are given adequate consideration by our most capable and far-seeing men; during the first few years after the War reconstruction should be limited to that urgently required for those who are without homes as a result of the War.

FORTHCOMING EVENTS

(Meeting marked with an asterisk is open to the public)

Saturday, October 17

Nutrition Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11 a.m. and 2.15 p.m.—Conference on "Trace Elements in relation to Health".

Sunday, October 18

Association of Scientific Workers (South Wales Area) (at the Royal Hotel, Cardiff), at 10 a.m.—Conference on "Science for Victory".*

Monday, October 19

Tercentenary of the Invention by Blaise Pascal of the Calculating Machine (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 12.30 p.m.: Luncheon; at 3 p.m. to 6 p.m.: Exhibition of Calculating Machines.

Friday, October 23

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Presidential Address by Colonel S. J. Thompson: "Boilers—Past and Present".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Teacher of Engineering Drawing and Science at the Castleford Whitwood Technical College and Junior Technical School—M. G. Swaine, Education Offices, Smawthorne Lane, Castleford, Yorks. (October 20).

Research Assistant (graduate in Science or Agriculture)—The Secretary, National Institute for Research in Dairying, Shinfield, Reading (October 21).

Teacher of General Science Subjects in the Junior Technical Department of the Mining and Technical College—The Principal, Technical College, Church Street, Barnsley (October 23).

Second Technical Assistant (male)—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow (October 24).

Clinic Psychologist (woman) at the St. Andrews and Dundee Training Centre—The Director of Studies, Training College, Park Place, Dundee (October 24).

Lecturer (man or woman) in Mathematics and Physics—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (October 31).

Lecturer in Engineering Subjects at the Medway Technical College, Senior Departments, Gillingham.—The District Education Officer, Fort Pitt House, Rochester.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Bibliography on Welding in Aircraft Construction. (B.7.). Pp. 10. (London: Institute of Welding.) [229

Industrial Practice for Spot Welding Light Alloys. Prepared for the R.52 Sub-Committee on the Spot Welding of Light Alloys by a Panel R.521 on Technique for Spot Welding of Light Alloys. (T.8.) Pp. 12. (London: Institute of Welding.) [229

British Council Map No. 1: Europe and the Middle East. Scale 1 : 11,000,000. 30 in. × 24¾ in. Printed in six colours. No. 2: The Far East. Scale 1 : 11,000,000. Outline edition. 30 in. × 24¾ in. PHYSICS D

THE CHURCH AS A SOCIAL FORCE

THERE is now widespread recognition that our enemies in this War derived no small share of their strength from their enthusiastic belief in the Nazi and Fascist doctrines which their leaders have inspired. Perverted though these beliefs may be, dangerous and destructive to the finest elements in the spiritual and moral heritage of mankind as these doctrines are, they are none the less held and propagated with the zeal and fervour of a crusade. They cannot be overthrown without a like enthusiasm and intense conviction on our part. The religious faith of the Nazi must be countered with one equally strong and equally capable of fostering devotion and loyalty and commanding sacrifice.

That is one reason why morale is so important in our war effort. Without a full understanding of what is at stake, without real conviction as to the supreme value of those ideas of freedom of thought, of speech, of worship, of association and of investigation which are inherent in the way of life for which we contend, there can be neither the spirit of willing sacrifice, nor the stern endurance demanded either for the speedy overthrow of Nazidom or to support the rigours of a long struggle.

It is futile to attempt to separate the weaknesses which, despite the great achievements of Britain, are disturbingly evident here and there to-day from the cynicism and moral inertia which have held so large a sway in our democracies during the twenty years uneasy armistice. Too long have we derided or despised the very qualities which are the secret of survival in war and in peace. That, far more than our failure to recognize the material menace and to rearm in time, has been our real weakness. This lack of courageous leadership had led to recognition of the need for a moral and spiritual revival long before the fall of France. The need for a moral basis for our war effort has been urged repeatedly since, in such striking books as Mumford's "Faith for Living" and Lord Elton's "St. George or the Dragon", and in a remarkable series of speeches of British and American leaders during the spring and summer of this year.

In the past two decades, man's scientific advance has dangerously outstripped his moral and ethical progress. To bridge the gap is the opportunity of science and religion. The antagonism between the two which marked some of the scientific advance has long since been replaced by the conviction that both have a part to play if man is to regain control over his environment and wield aright the immense powers with which he has been endowed. The conditions for a new understanding and a new partnership between science and religion are already being explored and the very hopes being entertained as to the new world order to be established after the War only make that understanding and partnership more evident.

Whatever the divergence of views as to where the moral basis of our society is to be found, there is no dissent from the necessity of finding such a basis. Moreover, both science and religion have learnt that it is in a democratic order of society that they can find their essential freedom and that their own advance is bound up with the defence of democracy and its adaptation to meet the problems of to-day. Men have come, too, to recognize that they need some living torch to rekindle the flames of devotion, of sacrifice and service, an abiding vision of eternal truths established by human experience, by which to set their course, and some fellowship whereby they can strengthen themselves, face the difficulties and disappointments, the dangers and tragedies which beset their path.

To that recognition the interest aroused by the great meeting at the Albert Hall on September 26, or indeed in the Malvern Conference on which it follows, as well as in the religion and life campaign, bears witness. There could be no more fitting time for the Church to declare the principles which should govern the ordering of society, and what the leaders of the Church may say as to the Christian basis of social reconstruction will be the more readily listened to now that the creation of the British Council of Churches has demonstrated that denominational differences will no longer block co-operation in social work. It is widely recognized that the Church should lay down principles for the conduct of individuals. As the Archbishop of Canterbury pointed out in his address, it is no longer tenable that such principles should not be applied to the groupings in which the lives of individuals are conducted. The Church has not only a right but also a duty to declare the principles of true social life. "What has lately been questioned—though by no means always in the history of Christendom—is the right of the Church also to lay down principles for the conduct of great corporations of people—trade unions, employers' federations, national States, and the like—and to exert its influence not only upon the way in which men and women behave in society, but upon the structure of society itself. But that division between the individual and the social groupings in which our lives are conducted is quite untenable. Our lives are social through and through. It is possible, no doubt, to lay excessive emphasis upon the social as against the individual, as also upon the individual as against the social aspects of life ; but the two are intimately bound together, and whatever touches human life, touches both. . . . And so our first duty is always to proclaim the fundamental Gospel itself, and to call men to heed that, and then to draw out the judgments that are implicit in it upon the order of society we know, and indicate the direction at least in which it seems that our forward move must be conducted."

That much has been recognized by our opponents. It is one of the fundamental reasons for the persecution of the Church both in Germany and in the occupied territories, and for the attempt to suppress freedom of worship and of preaching. There, no less than in Great Britain, men recognize almost instinctively that there are practices in their order of society which are inconsistent with what they have learnt of Christianity, which are contrary to the best that they know, and men have shunned the truth because their works have been evil. The Archbishop of Canterbury directed attention to two points in the ordering of our own society in respect of which the judgment of the Church must inevitably be uttered in condemnation, and they are worth examination as indicating the limitations and difficulties which beset the attempt at a Christian ordering of society.

The first of them is the broken fellowship of our society—what Disraeli in "Sybil" described as "the two nations". Resting upon the materialism of our habitual outlook, it leads to a gross disparity of wealth and poverty which must at all costs be remedied. "So soon as we all desire that every man should have enough before each of us should himself have any superfluity, of course everyone would have enough. If we cared more for justice than for comfort and for luxury, economic distribution would be well on the way to solve itself. There would still be problems to be worked out : we should need the skill of the economists and of administrators ; bu they would find no insuperable difficulties." Such broken fellowship leads also to a lack of leisure which in an age of mechanized industry involves lack of opportunity for a fully human life. To provide for all adequate leisure, with the means to utilize and enjoy it, must be one of our primary aims.

The second point stressed by the Archbishop of Canterbury is another expression of this principle The predominant motive guiding not only the enterprise but also the whole ordering of industry has been what is commonly called the profit motive. This is not simply evil : it can have its own place ; but tha is not the first place, where it may lead to an ordering of economic life which is in fact damaging to th general interest. The report of the Barlow Commission on the distribution of the industrial population could well be cited as evidence of the justice of this contention, and it is noteworthy that the recently published report of the Uthwatt Committee lay down principles in regard to the ownership of lan which clearly embody the Christian conception o stewardship rather than exclusive use. They aim at a combination of the advantages of public ownershi and ultimate control with private initiative, and w should see that they are not whittled away by concession to vested interests.

The Archbishop of Canterbury then suggested that we should seek to organize life so that self-interest may prompt the actions which are of the greatest social service, and after a passage referring to mone and credit in which a rather incautious reference to the banking system has led to some misunderstanding and given his opponents a handle for attack, he developed the major argument that it is for th Church to summon men to a dedication and a fellowship in which social life and worship are linked and men catch the vision and receive the power to rene and rebuild the whole of life. Whatever may be said of Dr. Temple's excursion into the realms of hig finance his speech will be welcomed by the va majority of the nation as evidence that the Church conscious of its great responsibilities, and that it prepared to speak plainly and is not afraid to condem social evils, which should not be tolerated by tho who have a living faith in the Fatherhood of God.

In regard to Dr. Temple's first point, the evil of wide disparities of wealth and poverty is generally recognized. The removal of such disparities is implicit in the sixth point of the Atlantic Charter and in the third freedom of President Roosevelt. What should be noted, however, as Dr. E. Barker emphasizes in a significant passage in his "Reflections on Government", which analyses Disraeli's conception of the two nations, is that no community is really arranged in a number of distinct and distinguishable classes. Social facts do not warrant the belief that there is any unbridgeable gulf between the different social elements present in the modern State.

Here then science and the Church are proclaiming the same truth, and one which as Dr. Barker shows is vital to the existence of democracy. Without it the presuppositions of democracy vanish. There will be no single society; no common terms of debate; the differences of opinion and policy will be too acute and too deep to be bridged. While lifting up her voice against social evils therefore the Church must emphasize her call to a fellowship of service which will give a vision and a sense of values transcending all the numerous divisions and subdivisions which make up society. The driving force of religious conviction and the passion for righteousness must reinforce the execution of our planning as well as guide and inspire its framing.

For that reason alone we might welcome this fresh demonstration that the leaders of the Church are not concerned solely with ecclesiastical matters but also with establishing the social conditions which promote right relations both between man and his Maker and between man and his fellows. If they address themselves to that task with intelligence and knowledge as well as devotion, the Church may do much to assist the cultivation of that temper of accommodation, good sense and persuasion which, as Dr. Barker emphasizes, are essential if democracy is to work. The ultimate issue which confronts us transcends any difference between classes, between parties or parts or sections of the community. It is a war between two mental worlds, between two different spirits and tempers of mind—between that of accommodation and that of intransigence.

The Church and science clearly stand on the same side in that struggle; both have learnt to be patient and tolerant of differences, to accept them as the necessary ingredients of unity, and to seek to achieve it by the method of voluntary adjustment. Where science will supply the untiring dispassionate search for truth, the Church can supply the dynamic passion for righteousness which will see that justice is done. Together they should assuredly prevent that débâcle of cowardice and stupidity on the part of political leaders which was so largely responsible for the disaster of the present War. Prof. Gilbert Murray's comments on public opinion in his article, "The Inevitable League", in the current number of *Agenda* should not pass unnoticed in this connexion.

But there is yet another reason why the emergence of the Church as a social force should be welcomed. It is an indication of a revival of the adventurous spirit which is characteristic of the great ages, as Whitehead reminds us. What is required to-day is not merely moral courage and conviction and the vision of a new order, or even a quickened sense of spiritual values. It is also that spirit of adventure which has been ever characteristic of the advance of science itself. Society cannot move forward unless men are willing to try new ways and to explore new ideas, with all that that implies in breaking with the ways of life or habits of thought of the past. The great days in the record of the Church itself have always been those in which she rose to the challenge of one great opportunity and staked her life on some brave new venture.

No new social order will be built unless we are willing to run risks in the building of it and it is all-important therefore to carry with us into the task those who are ready to risk losses. It should not be forgotten that readiness to risk losses rather than the greediness of individuals for profits has been the mainspring of a free and competitive economy, and that factor must find its due place and expression in our new order though it need not be the first place. What is imperative is that the Church and society must be mindful of their duties as well as of their rights.

That was the central theme of Sir Stafford Cripps's address on "The Challenge of Christianity". While it is not the function of the Church as an organized body to enter the lists of the political parties, to do which would confuse the issues and jeopardize the power of religion, it is for the Church to provide the moral force and the driving power for social and economic development. Christian principles, he urged, should be made so to permeate public opinion that no Government can act against them, and those principles must be related to the social and economic problems of the moment.

The interpretation of the Christian ethic in relation to the present facts of life for which Sir Stafford Cripps calls demands not merely courage and firmness of purpose, but also lucid thinking, and the strength of the leadership of the Church will depend upon the measure in which these qualities are forthcoming. Moreover, like Gilbert Murray, he reminds us pertinently that leadership does not consist in seeking to interpret and then to follow the wishes of the majority, but rather in the attempt to lead and direct popular thought along the channels of wise action. Never more thoroughly than in our recent history was there demonstrated the truth of Sir Walter Scott's dictum that without courage there can be no other virtue, and this is true also of the Church. The fear that the bold teaching of Christian principles and their application to our present society will create a demand for far-reaching social and economic changes which may undermine the finance and organization of the Church itself must be cast aside.

Rejection of the Nazi materialistic conception of society and insistence upon the dignity of human life and the right of all persons, whatever their class, creed or colour, to contribute to the development of our common civilization, which follows from the basic Christian doctrine of the brotherhood of all peoples, will, however, make demands on us all, not merely on our leaders. The call for self-sacrifice may well be greater and will certainly be no less when the War ends than it is to-day. The establishment of social justice calls for endeavour at least as strenuous and whole-hearted as that now demanded to win the War, and it is only in a democratic way of life that the Christian conception of brotherhood can find full expression in our national life.

The precise form of our democracy may be a matter for experts rather than for individual Christians as such to determine and there can be only confusion if the Church through its leaders or through individuals attempts to pronounce on technical details. The difficulty in drawing the line is of course one of the major problems in such a movement as that which was launched by the Albert Hall meeting, but beyond the broad principles which should be included in a democratic society the Church has a right to indicate immediate and practical objectives in the field of social and economic justice. Moreover, it is its duty to test the proposals which may be advanced by others and to examine how far they serve the principles declared and are in harmony with the spirit and ideals for which the Church stands.

These practical objectives should, as Sir Stafford Cripps pointed out, at least include the five simple desires desiderated by President Roosevelt in his speech to Congress last year when he enumerated the four freedoms. Equality of opportunity for youth and others; jobs for those who work; security for those who need it; the ending of privilege for the few and the preservation of civil liberties for all—these are based upon elementary principles of Christian justice but their attainment makes personal demands on all. Great changes in the planning and organization of production may be involved in the provision of jobs for all. The ending of privilege requires the surrender of our own privileges with the rest, not excluding that of endowment and establishment for the Church. Equality of opportunity for youth means that our children must share a common system of education with those of all others, and if security is to be given to all who need it, the sacrifice of many non-essentials by us may be required to provide with certainty the essentials that others require.

In this task the place of education is fundamental. The mistakes in making the peace after the War of 1914–18 may be repeated unless men and women are educated as to the sacrifice and effort that will be required of them and not merely of others even to establish the four freedoms and serve such simple basic needs. Moreover, men and women will not fully answer that call to self-sacrifice and service unless they understand with their minds something of what is demanded of them. The new vision must be seen in the schools and the new values learnt there as well as proclaimed by the Church if we are to see a new and nobler order of society in which our democratic institutions are renewed and revived by the ideals and ethics of Christianity.

There is therefore every reason to welcome this demonstration that the Church recognizes the challenge of the age and is accepting the responsibilities which are hers in this task of reconstructing society. There can be no misunderstanding of the difficulty of the task of convincing the world that no private or selfish interest should be allowed to thwart the full application of the principles in which we believe. Courage and example as well as precept and steady, untiring pressure will be required for success in this warfare also; and there are the further difficulties inherent in the appeal to moral and spiritual values where terms are ill-defined and easily misunderstood.

The task is, however, one for action as well as for lucid thinking. It is the old problem which scientific workers have reason to know too well of the relating of knowledge to action. Even the calm, serious spirit of science with its tireless quest for truth, while it can give men the knowledge they require to build a new world, cannot supply either the wisdom or the driving force to ensure that that knowledge is used aright. We need the inspiration which comes from a quickened sense of the enduring human and spiritual values in man's great heritage now imperilled by the paganism and barbarism which has broken out in Europe and in Asia alike. Neither the Archbishops nor Sir Stafford Cripps would claim that all those values are derived from Christianity alone, though they might well claim that in Christianity we have learnt to give them a fuller and less academic meaning. At least we may hope that the campaign thus launched may give men and women a new sense of the enduring values of life out of which may spring a firmness of purpose, a vision and judgment which will inspire alike the wisdom needed to guide our use of knowledge and resources and the courage and self-sacrifice required to fulfil all our hopes of a new order of the world, which will not merely be recompense for the present sufferings but also be worthy of the best in our moral and spiritual heritage.

POLITICS AS A PROFESSION

Return to Reason!

An Essay in Political Diagnosis. By Geoffrey Bourne. (Hutchinson's Booklover's Library.) Pp. 64. (London, New York and Melbourne: Hutchinson and Co. (Publishers), Ltd., 1942.) 2*s.* 6*d.* net.

WHETHER we like it or not a new order is coming. By this I do not mean the curious political philosophy paraded under that name but the changes brought about by the strong acid solvent of a great war. The Napoleonic wars spread throughout Europe the principles of the French Revolution; Alexander left Greek culture behind in India. The very violence of this present conflict will eat away the dry rot of many an old privilege and outworn allegiance. Mankind learns quicker to-day; the higher intelligence quotient of the average man gives a better spring-board for the start off. While admittedly the human animal would seem slow at its lessons it is not altogether a dullard, and war, as I have said, acts as a powerful tonic.

Among the many aspects of human life awaiting overhaul, an important one is the system of government. Problems of this nature resolve themselves fundamentally into the relations between public interest and private right; they are concerned less with the individual as such than with his place as a social unit. And the old order changeth; frictions that were at the best tolerable before have taken on a fresh keenness, a new and sharper edge, from the rise in mere bulk of population, the swarming multitude pressing outward with a swelling intensity to a place in the sun. There are, of course, other angles to the situation but it is the swift rise in numbers alone that adds a strident urgency.

Agreement has been very generally come to on democracy as the most satisfactory system. Plato said something about it when the great centres of civilization were a few Greek villages. Recent thought, such as Ernest Barker's notable contribution, does but give the same principles a greater detail. But a democratic government, while it does mean majority rule, while it does concede certain formulæ of social contact, has to obtain specific form, has to be deputed into administrative, legislative and judicial expression. The mob in Athens might frequently enjoy debate, the mob in England can only go to the hustings on a rare occasion.

Here in Great Britain circumstances, historical and geographical, have led to the development of a political structure, offering in the past a satisfactory adaptation to the needs of our social life. The two-party system which is an accepted part has been found reasonable in theory and convenient in practice; it has allowed for much that is flexible and plastic in detail upon a framework that is rigid and defined.

But the anachronisms, the inequalities, the stupidities, the creaking of the joints so audible at every step that were well enough for England in Tudor, in Hanoverian or even in Victorian days, are no longer admissible to-day. The man in the street, the common man, you and I, everyone of us, wants and wants here and now, the same competence and efficiency in government that we see in every department store or railway company. The difficulty is how to do it, how to improve upon existing arrangements, not abruptly or violently but sanely and soberly, commensurate with the reasonable needs of forty million people.

This is the problem which has been taken up by Dr. Geoffrey Bourne in "Return to Reason". The author is a medical man; he specializes in cardiology and is on the staff of one of the great teaching hospitals in London. In his own line he holds a distinguished position, one of an eminence shared by very few in England. He is thus able to bring to a subject, admittedly foreign to his own but one of serious import to everyone, a trained and disciplined intelligence. More than that, an attitude of mind accustomed to weigh and consider the interplay of circumstance and to seek at all times a balanced and considered judgment.

"Return to Reason" is a remarkable book. It offers an ordered study of the political situation in England to-day and submits a thesis of modifications practicable at an early moment and reasonable in design and detail. It is radical but not revolutionary. The writer allows his brush a bold sweep; he would certainly agree that people get the Government they deserve, for it is on this basis that he builds up his argument. He does not seek to apportion petty blame but explains how the choice of the ordinary man deriving rather from the heart than the head must have certain logical results.

This breadth of approach to a very large subject necessarily restricts the attack in depth but it is obvious that this has been so intended. He has deliberately sought to reach the notice and hold the attention of everyone capable of consecutive thought above matriculation standard, a width of appeal demanded by the importance of his subject and its very general concern. The book is free from the polemics of the tub-thumper and from meretricious argument slurring over faulty premisses. It is, in short, an attempt to approach politics from the point of view of the adult man who asks nothing more than the Government he would give himself. It is on some such basis, not necessarily of detail but of the underlying attitude of "Return to Reason", that we can and should take up the responsibilities of a better arrangement of our social life.

Dr. Bourne believes in democracy but qualifies his belief by reminding us that "democracy is not an easy form of government". He points out that the serious use of the function of intelligence on the part of the governed is essential if participation in the actualities of government is to be a reality and not an agreeable fiction. The author, therefore, to develop his subject logically, devotes his earlier chapters to explaining how easily man is swayed by his emotions, how powerful they are, how difficult it is for anyone to remain detached, cool and sane in a welter of conflicting ideologies and breathing constantly an atmosphere tainted with thalamic urges. It is so much easier at the end of a heavy day to swallow wholesale the glib propaganda of the electioneering agent. It is so much easier to be Conservative with a capital C than to bother thinking out seriously national concerns. Dr. Bourne takes pains to indicate, in the structure of the human mind, the strength, the vehemence, the overwhelming intensity of the mass of crude emotions that rule the ordinary man. But he submits that, be that as it may, man has shown the capacity of sustained thought, the inclination to recognize his primitive side as irrational and impulsive and the desire to subordinate it to the control of his intelligence.

Guidance on these lines may be found in the analogy of the professions. In them, all of them, the dominant note in their educational scheme is the development of an attitude of mind giving a true value to reason, to literal fact and to logical argument. That so many men can and do live lives consistently governed by such a code, that they can find themselves rising above the bonds of time and circumstance, of personal welfare, of national differences, into an atmosphere where all can meet in easy fellowship on a plane of a consuming unity of interest over-riding all other considerations whatever as in the scientific world, holds out the promise of what man will yet become.

Dr. Bourne goes still a further step; he not only accepts democracy, he also thinks the British system a workable one. He is, in short, intent on being practical, he would make bricks with the straw we have. He points out the flaws in the system as it is at present practised. These we all know. Influenced and rightly so by on one hand the pressing need for serious, sober, scientific consideration of many social difficulties, and on the other hand by the system of training that has proved such a stimulus to the practice of medicine, he submits that the practice of politics would be materially improved by being turned into a profession. By this he by no means refers to the professional politician of to-day who is only the equivalent of the quack in medicine, but suggests that a similar standard of educational attainments in the many branches of knowledge advantageous in politics could be arranged and that it would be likely to produce the type of man who would on one hand represent adequately the electorate and on the other hand be capable of debating or discussing the manifold complexities of government. A professional standard, certain recognized qualifications, are rightly expected from a teacher, a dentist, a barrister or an accountant; the principle has been particularly successful in these instances, in the sense that it has brought proper service where it was needed, that it has been to the public interest, and that it has tended to heighten in the members of these professions both the moral sense of honourable duty and the scientific search for truth.

Dr. Bourne would like to see the practice of politics subjected to the same educative influences, the same increasingly exact standards that have raised and dignified the other professions in England. The central idea is sound, there are many obvious points in its favour, and the arguments with which he buttresses his case are carefully set out, logical in arrangement and appealing in conclusion.

"Return to Reason" is a competent and careful contribution to current political thought. It indicates a step in electoral procedure, advantageous in every way to the interest of the intelligent voter. Some such change is clearly imminent; a solution on these lines would at any rate give more flesh and bone to a system involving the apparent inconsistency of ruling by the ruled.

JOSEPH GEOGHEGAN.

THE STUDY OF DECAPOD LARVÆ

Larvæ of Decapod Crustacea

By Dr. Robert Gurney. Pp. viii+306. (Ray Society Volume, No. 129, for the year 1941.) (London: Bernard Quaritch, Ltd., 1942.) 25s.

LITTLE more than a century ago Vaughan Thompson showed that a decapod crustacean leaves the egg in a form very different from its parent—a discovery received with incredulity by many well-known zoologists. The fact once accepted, developmental studies have steadily progressed. Claus stands out in his comparative work and, later, G. O. Sars laid the foundation of accurate knowledge of larval stages. In those days there were no facilities for rearing larvæ and the stages were picked out of the plankton and the life-histories pieced together from live or, more often, preserved material. Expeditions, from the "Challenger" onwards, brought back unknown larvæ, often from deep water, and these were frequently described as distinct genera. The collections, necessarily always preserved, contained many imperfect specimens.

With modern research and marine laboratories a very different state of affairs offers itself, and the specialist can collect his own material alive and keep it alive over periods of moulting; or hatch the larva from the egg. Gurney's work is of this kind. He has described larvæ from all over the world, giving special attention to the British species at Plymouth and to those from the Red Sea and Bermuda. This intensive work on the live animals has resulted in a large addition to our knowledge. In 1924 he published in the "Terra Nova" Reports a general account of the decapod larvæ, for the first time bringing all together and summarizing the subject. This was followed by the valuable series of monographs in the "Discovery" Reports, and many papers were published in various journals. With such experience based on so much field work this book should be, and is, full of new ideas. A glance at the systematic portion shows how much we have progressed since 1924.

Of importance is the placing of the Euphausiacea definitely in the Decapoda. It has gradually come to be accepted that the two groups are nearly related, the resemblance between the Euphausiacea and the Penæidea being remarkably close, both retaining many characters regarded as primitive. In discussing the larval stages the view is held, and with good reason, that stages 1 to 3 of the normal Caridean development represent the three protozoeal stages of Penæidea and the three Calyptopis stages of the Euphausiacea. Also that the stage passed through in the egg and sometimes surviving into free life in the form of the embryonic cuticle represents the nauplius and not the protozoea.

It is emphasized that the fundamental fact which determines the organization of the larva is the division of the stages according to their method of swimming. In the nauplius the main organ of locomotion is the antenna as in the primitive Branchiopod, and in the protozoea of the Euphausiacea and the Penæidea it still has that functional importance. In the decapod larva later than the nauplius and protozoea, thoracic locomotion replaces it; in the moult to post-larva, abdominal propulsion takes its place. Thus decapod development is regarded as made up of four phases of phylogenetic significance: nauplius and protozoea with antennal, zoea with thoracic, and post-larval with abdominal propulsion.

New light is thrown on the much-discussed question of giant larvæ. Gurney's recent work on Procletes has proved that it is the larva of Heterocarpus. If this, the largest decapod known, can be accounted for, it is probable that most of the other out-size larvæ will turn out to be ordinary larval stages of known or unknown genera. Nevertheless, it is shown that many larvæ, especially those from deep water, may continue to moult, as larvæ, much beyond the time of normal metamorphosis, and in the sense that they failed to metamorphose at the proper moment, but have continued to moult, may be regarded as abnormal.

Whenever and wherever detailed work is done on decapod larvæ, it is found that there are many more species than there are adults to fit them. This means that there are many undiscovered adults. Lurking in habitats difficult of access, there must be many unknown forms. It is often by means of the larvæ that new adults are discovered, which proves that there is some importance in larval characters as a help in making natural classifications. There is no undue optimism in the present work as to the value of the larva in systematics, according to our knowledge up to date, although it is shown that in some groups the larvæ point to drastic changes. This is specially the case in the Oxystomata, which cries aloud for revision. The conclusion is reached that "the evidence from development so far accumulated has not produced any very serious contribution to the systematics of the group". In spite of this statement, the systematic portion of the book shows that we can usually place a larva more or less accurately in its proper position, although there are still many mysterious forms. The answer to it is that we do not yet know enough and that we must go on working, and we look forward to the time when all systematic work will include both larva and adult, and a truly natural classification will result.

Apart from the number of biological problems which arise from the study of decapod larvæ and their systematic interest, they are of much importance economically. For the fisheries investigator a detailed knowledge of the life-histories of all those of food value is essential; for the oceanographer the study of currents is materially helped by their accurate determination. The book bristles with problems. It is indispensable to all specialists on the subject, to the general zoologist and to the student.

The illustrations, in pure outline, are exactly suitable to the subject. With the exception of one or two, they are all original and have not been published before. The form of the volume is in every way as good as usual, and the Ray Society is to be congratulated on the production of such a volume in these difficult times. The companion volume by Gurney, "A Bibliography of Decapod Larvæ", was published by the Ray Society in 1939.

THE HUMANITIES OF CHEMISTRY

Collateral Readings in Inorganic Chemistry

Second Series. Edited by L. A. Goldblatt. Pp. viii+198. (New York and London: D. Appleton-Century Co., Inc., 1942.) n.p.

In a rapidly changing world the whole system of education must come under review and the teaching of science cannot escape. The ideal surely is a cultural background as full as possible and a training which produces a graduate able to think both critically and constructively, with a wide knowledge of his subject. A student who has devoted his energies mainly to the memorizing of facts, largely for the purpose of passing examinations, and is in truth little more than an encyclopædia bound in skin with all the inaccuracies of such treatises, is likely to disappoint both himself and his employers when he goes out into the world.

The problem is how to teach the mass of facts which constitute a science and at the same time show the student that the subject is real and human, even exciting when viewed from a little distance, far enough to forget the menace of an examination. Fifty years ago, when there was less to master, there was much more time for original reading. Most of us then read all we could lay our hands on, both the current journals and the classic papers of the past. They were longer but far more colourful, especially when polemic. We read about subjects remote from our own particular researches, and the chemical world was made real to us, a pleasure not a task.

This is admittedly impossible to-day, the literature is so large; moreover, the need for condensation makes most papers unreadable except by experts in the particular field. How is the student to gain an idea of the broader implications and humanities of his subject?

One answer is provided by the "Collateral Readings" edited by Mr. Goldblatt. He has reprinted and collected under one cover some thirty-six articles in inorganic chemistry by many of the leaders in the United States each of which is essentially stimulating, even exciting, and can be classed as leisure reading and not work. The first article is Bogert's "From the Cradle to the Grave", one of the best expositions of what applied chemistry is doing and can do ever written; the others cover specific industrial subjects such as bromine or magnesium from the sea, argon, radium, phosphorus, sulphur; more theoretical subjects such as atomic weights, the periodic system, electrolytes, the polar molecule concept; or general questions like text-books and abstracts. The whole volume has a definite commercial flavour, for American chemists expect to enter industry and make their contribution to the world's progress in industrial research laboratories. They are unaware that this is still regarded in England as not quite the thing.

Taken as a whole, the articles are well selected and make first-class reading: there can be few chemists in Great Britain who would not gain from reading them. Any student who really intends his chemical studies to be serious would be bound to benefit from them and should find them far more exciting than any crime novel, of which there are so surprisingly many on both sides of the Atlantic.

E. F. Armstrong.

A NEW SOCIAL SURVEY

Nutrition and Size of Family

Report on a New Housing Estate, 1939. Prepared for the Birmingham Social Survey Committee by M. S. Soutar, Dr. E. H. Wilkins and Dr. P. Sargant Florence. Pp. 50. (London: George Allen and Unwin, Ltd., 1942.) 2*s*. 6*d*. net.

The social, economic and environmental changes produced by the War have not so far invalidated the major findings of pre-war social surveys. The social statistics made available by the investigations at York, Bristol, Merseyside, Tyneside and other inquiries will be of value to those concerned with reconstruction. To the existing corpus of knowledge we now have to add an excellent little report prepared by the Birmingham Social Survey Committee. This report breaks new ground. Not only did the Survey set out to ascertain the extent of poverty in families of different sizes (only families with children were studied), but also it attempted to find out the adequacy of income as measured by the amount of housekeeping money in the hands of the housewife. The adoption of this realistic approach showed a startling increase of poverty with increasing family size. Thus the proportion in each group below sufficiency were: with one child 13 per cent, with two children 45 per cent, with three 65 per cent, with four 85 per cent, with five 96 per cent and with six or more 96 per cent. This method revealed that *actual* poverty is much greater than is disclosed by the type of measurement hitherto adopted in social survey work.

This study, which relates to a new housing estate outside Birmingham, was carried out in mid-1939—a period of relative prosperity. In addition to its many interesting findings, the Survey shows that bread consumption rose after rehousing. Town planners should note that, as an independent social reform, rehousing has its limitations.

POTATO VIRUS DISEASES

By F. C. BAWDEN

Rothamsted Experimental Station

THE degeneration of the potato seems to have been unknown in Europe before about 1770, but after that it rapidly assumed such proportions that by 1780 farmers in some districts had to abandon potato growing, and prizes were offered to those who could find the cause and devise a cure for this serious affliction of so important a crop. For 150 years there was continual speculation and controversy about the cause of this degeneration. Some shrewd observers drew deductions that recent work has fully confirmed, but in the absence of any direct experimental evidence the most widely held view was that potatoes degenerate because they are weakened by continual propagation by 'unnatural' asexual methods. Only within the last twenty years has it become clear that degeneration is a result of plants becoming infected with one or more viruses, which are handed on to the progeny through tubers, but rarely, if ever, through the true seeds. If one can judge from the size of the audience at a discussion on this subject, arranged jointly by the Association of Applied Biologists and the British Mycological Society*, on October 9, this advance in our knowledge has certainly not lessened interest in the problem.

Many early writers noticed that potatoes degenerated more rapidly in some districts than in others, and a few suggested that there was some correlation between degeneration and infestation with aphids. Long before virus diseases were recognized, some growers in the south and east of Great Britain regularly obtained new supplies of seed from the north and west, and in this way avoided serious losses. With the discovery that the most destructive virus diseases are transmitted by aphids, and that the weather in the north and west usually inhibits the multiplication and movement of aphids, this method of control has been increased enormously. Steps have also been taken to improve on the natural advantages of these districts. The crops are examined periodically and diseased plants removed; they are also inspected and awarded certificates of health stating that they contain less than a small percentage of infected plants. Mr. G. Samuel stated that at the present time something more than 300,000 tons of such certified seed is imported into England from Scotland and Ireland each year. Within two or three years this has become valueless for seed purposes, and he described this wastage as our most important plant pathological problem.

Some twenty viruses that affect the potato have now been described, but in Great Britain most of the losses are caused by three: leaf roll, potato *Y* and potato *X*. These differ strikingly from one another in their behaviour, and Mr. F. C. Bawden showed that conditions favouring the spread of one might not favour the spread of another. Even with viruses transmitted by aphids this is true, for the relationships between different viruses and their vectors differ. For example, aphids become infective with leaf roll only slowly; a day or so must elapse after they have fed on a diseased plant before they can infect a healthy one, but once they have become infective they go on being so for the remainder of their lives. Mrs. M. A. Watson has shown that the position with potato virus *Y* is very different. Aphids can transmit this virus immediately after feeding on a diseased plant, and, oddly enough, they transmit more readily if they are first starved and then fed for only a few minutes on a diseased plant. Such aphids also remain infective for only short periods, sometimes minutes and never more than hours. These differences offer an interpretation of the fact that, with crops in which both viruses are present, one may spread considerably while the other does not. For the slow-moving, wingless aphids would seem ideally suitable for spreading leaf-roll, whereas the winged migrants are much more likely to fulfil the requirements for transmission of potato virus *Y*.

Scotch and Irish stocks owe their superiority to their relative freedom from these two aphid-transmitted viruses, for even the best of these stocks are often infected with virus *X*. In many varieties this produces a mild mottling of the leaves, insufficient to be noticed readily, especially if all the plants are uniformly affected. In spite of the slight leaf symptoms, various workers have found that such infections can reduce the yield by 20 per cent; this is small compared with the 50–90 per cent reduction found for different varieties with leaf-roll and severe mosaic, but is nevertheless considerable. There is, therefore, still room for improvement in our certified stocks. The method being tried is to test individual plants of established varieties until some are found free from this virus and then multiply these as nuclear stocks to replace those now grown. Some of the difficulties of this method were described by Dr. Kenneth M. Smith. With many of our commercial varieties it has so far proved impossible to find a single plant uninfected. But even when this first difficulty is overcome, the problem is by no means simple. We know no insect vectors for this virus, and we are still largely ignorant of what precautions to take to keep such plants healthy. Workers in Ireland find that healthy plants can become infected if their leaves rub against infected plants, but there is some doubt if this method of spread could account for all infections. Virus *X* is found in crops other than potatoes, both under glass and in the field, and healthy potatoes in insect-proofed glasshouses are not always safe against it. It is obvious that the multiplication of stocks free from this virus is important; but before it can be embarked upon on a large scale further research is needed on the conditions that lead to infection.

Although Scotland and Ireland produce most of our best potato seed, they have no monopoly. On the wind-swept hills of Wales, Cumberland and Devon and Cornwall aphids are also rare, and in these districts there are now flourishing associations for the production of certified seed. The oldest of these is in North Wales, where for fifteen years Dr. T. Whitehead has maintained the same stocks in a state of vigour. Over this period he demonstrated a close correlation between aphid numbers and the health of the stocks, and only in a few exceptional years in which aphids have multiplied excessively has there been any difficulty in keeping the health of stocks up to the standards for certification. The most important aphid is *Myzus persicæ*. Its normal method of overwintering is in the egg stage on peach trees; but it can also survive in the adult form under glass and, in favourable conditions, in the open on cruciferous crops, especially savoys. In North Wales, where there are few peach trees, Dr. I. Thomas considers that the degree of infestation of the potato crop is largely determined by the severity of the—

---

* It is hoped that the proceedings will be published in full in the February number of the *Annals of Applied Biology*.

previous winter, for only when conditions favour overwintering out of doors are the numbers of aphids large. The importance of the method of overwintering is also shown by *Aphis rhamni*, which in this region is found in numbers only in the few localities where the winter host *Rhamnus catharticus* occurs.

In East Anglia conditions are very different. Mr. J. P. Doncaster finds that *A. rhamni* is the commonest aphid on potatoes, and frequently reaches an average of more than a hundred per leaf. Fortunately, this aphid does not seem to transmit leaf roll. As it moves about less readily than *Myzus persicæ*, it is probably less important as a vector, but it is likely that the migratory forms play a considerable part in the transmission of potato virus *Y*. Overwintering on Brassicæ seems to be rare in East Anglia, but here there are sufficient peach trees and glasshouses to provide ample sources for *M. persicæ* in the spring. No attempts have yet been made to control the aphids by treating their overwintering sources, for example, by wholesale winter-washing of trees and fumigation of glasshouses; but Mr. Doncaster reported that on the potato crop a complete kill was obtained by fumigation with nicotine. The effects of the treatment, however, were only temporary, and the fumigated crop rapidly became re-infested from nearby sources not treated.

After examining many potato crops in eastern England, Dr. P. H. Gregory and Mr. Doncaster could find no simple correlation between numbers of aphids and amount of spread of leaf roll and potato virus *Y*. It seems likely that in these districts there are almost always sufficient aphids for rapid spread and that whether this occurs or not depends on other factors, probably those influencing the movement of the insects. In many crops in 1941 there was a striking difference between the behaviour of the two aphid-transmitted viruses. Potato virus *Y* spread only to a small extent and only early in the season, again suggesting a correlation between the winged migrants and spread of this virus. By contrast, the number of plants infected with leaf roll virus increased steadily throughout the season, and in some stocks with large haulms, in which movement of crawling aphids from plant to plant would be facilitated, the percentage of infected plants increased more than twenty times.

The ability of one and the same potato virus to produce different symptoms in different potato varieties greatly complicates diagnosis, but can also be of value in helping to reduce losses. Paradoxically, it is the most susceptible varieties that suffer least. Some British varieties, for example, King Edward and Epicure, die quickly when infected with virus *X*. Infected plants leave no viable tubers to act as further sources of infection, and the stock as a whole is safeguarded by the death of the individual. Similarly, other varieties are killed by infection with viruses *A*, *B* and *C*. In effect, such varieties do their own roguing, and Dr. G. Cockerham showed that the health of commercial stocks of these varieties is much better than that of those which tolerate infection. This hypersensitivity is inherited, and by crossing between different varieties, the Scottish Society for Research in Plant Breeding has produced Craig's Defiance, which dies when infected with any of viruses *A*, *B*, *C* and *X*, so that stocks of this variety remain virtually free from all four. Unfortunately, no varieties are known which are hypersensitive to leaf roll and virus *Y*, but after testing some hundreds of different varieties Dr. Cockerham reported that he had found some with a true resistance. As this is also inherited, it seems that the geneticist will begin to play an increasingly important part in combating potato virus diseases. However, no quick success can be expected by this method; also, viruses appear to mutate with such frequency that permanent success should not be expected either, as it is impossible to be sure for how long a new variety bred for some specific property will retain this in the field.

In an attempt to increase the health of crops from once-grown seed, the Ministry of Agriculture has since the War introduced a scheme whereby crops in England, grown from Scotch or Irish seed and planted fifty yards from other potatoes, receive a seed certificate. Mr. Samuel showed that the measure is meeting with some success, for such seed usually contains less than 10 per cent of severely affected plants and crops as well as new seed, but it does not greatly increase the useful life of the stock. One wonders whether the information we now have about potato virus diseases could not be still further applied. In normal times it may be that the import of new seed each year is the most economical control measure, but now the transport of 300,000 tons of potatoes is in itself a problem. In many parts of England it is likely that the growing of heavy crops of ware potatoes and the production of good seed are incompatible, for maximum yield is obtained only if the plants have a long growing period and this greatly increases the likelihood of infection. But crops grown especially for seed purposes could probably be kept in a good state of health for several years. These could be grown in isolation, possibly on some of the reclaimed land that cannot be expected to yield large crops, rogued, perhaps sprayed or fumigated against aphids, and the tops killed early in August, after all the tubers are formed but before virus diseases have had time to spread appreciably. The contributions at the discussion all suggested that this may be a practical control measure, but it urgently needs testing on a commercial scale.

VELOCITY OF RADIO-FREQUENCY WAVES*

By Dr. R. L. SMITH-ROSE
National Physical Laboratory

THE wireless engineer and radio physicist require to know the speed or velocity of electric waves in order, for example, to convert their measurements of frequency into the corresponding wave-lengths, while various methods of studying the propagation and direction of arrival of waves involve a knowledge of the wave velocity.

Apart from the various classical experiments on the velocity of light conducted during the latter half of the nineteenth century, the most comprehensive work on this subject was carried out by Prof. Michelson and his co-workers, and the most important part of these investigations were in progress when Michelson died in 1931. The equipment used in this work is notable by reason of the fact that the path traversed by the light waves was enclosed in a steel tube one mile long and three feet in diameter, this tube being evacuated to a pressure of a few millimetres of mercury. By multiple reflexions between mirrors set up in this tube, the light waves were caused to traverse a total path-length of some 8–10 miles in a vacuum before and after reflexion from a thirty-two-faced rotating mirror used to determine the time of travel of the waves over this path.

---

* Substance of the chairman's address before the Wireless Section of the Institution of Electrical Engineers, delivered on Oct. 7.

The development of radio-frequency technique has facilitated the measurement of the velocity of light on a laboratory scale by a method which has been used by W. C. Anderson and others. In this, the light waves are modulated at a radio-frequency of from 20 to 100 megacycles per cycle by their passage through a Kerr cell subjected to an alternating voltage at this frequency. Two portions of this modulated light beam are made to traverse paths differing in length by some 10–20 metres before being received on a photo-electric cell equipment used to measure the resulting intensity of the light received.

A summary of the most accurate measurements carried out by these two methods is given in the following table:

RECENT MEASUREMENTS OF THE VELOCITY OF LIGHT

Values refer to transmission in a vacuum

Date	Observers	Velocity in cm. per sec. $\times 10^{-10}$	Accuracy of measurement	Difference from $c = 3 \times 10^{10}$
1931–33	Michelson, Pease and Pearson	2·99774	0·4 in 10^4	$-7·5$ in 10^4
1936–40	Anderson	2·99776	0·5 in 10^4	$-7·5$ in 10^4

Since for radio purposes we are rarely concerned with wave transmission in a vacuum, the above values will require to be multiplied by $1/\sqrt{\kappa}$ where κ is the dielectric constant of the medium in question. For air under normal atmospheric conditions at the earth's surface in Great Britain, corresponding to a pressure of 760 mm. mercury, temperature of 15° C. and a relative humidity of 70 per cent, the value of κ is about 1·0007, and thus the corresponding value of the velocity will be reduced to $2·99670 \times 10^{10}$ cm. per second.

Our knowledge of the speed at which waves in the radio-frequency spectrum travel is much more limited and less precise. Until about 1935, most investigators in this field used methods which were not free from sources of error arising either from defects in the apparatus or from an insufficient knowledge of the actual path followed by the waves. More recently, some workers have used methods involving the setting up of standing waves in air or on wires, and compared the wave-length so obtained with the frequency of the oscillations given by the source. In 1937, W. Ross and E. C. Slow, of the Radio Department of the National Physical Laboratory, made a determination of the phase velocity of radio waves transmitted along the surface of the ground, using apparatus already developed and in use for other investigations. The average result obtained for this velocity over the wave-length range 20–120 metres (2·5–15 Mc./s.) was $2·95 \times 10^{10}$ cm./sec., the overall experimental accuracy of the measurements being considered to be about 5 per cent.

A most comprehensive investigation of the velocity of medium radio waves (wave-lengths 230–345 m.) was carried out during the years 1934–35 by a group of workers in the laboratories of the U.S.S.R. under the direction of Profs. L. Mandelstam and N. Papalexi; and the details and results of these investigations were published in a collection of papers in *Technical Physics of the U.S.S.R.* in 1937. The method employed comprises a determination of the time of transit of waves between a sending and reflecting station by measuring the phase difference between the two sets of waves, the ratio of the frequencies of which is rational. The subsidiary investigations included the development of methods and instruments for measuring the phase difference between harmonic oscillations of different frequencies, and the study of the phase displacement introduced by high-frequency amplifiers. The accuracy of the measurements depends essentially on the measurement of the two quantities, the phase displacement, and the length of path traversed by the waves between the stations. The total phase displacement used during the observations ranged from a few hundred to several thousand degrees, and the investigators were able to measure these to within 3° or 4°; so that the accuracy of phase measurement was of the order of one or two parts in a thousand in the most favourable cases. The distance measurements were carried out by standard geodetic survey methods, and appear in the most favourable cases to have been determined to an accuracy somewhat better than one part in a thousand (0·1 per cent).

The mean results obtained in the various sets of experiments for the velocity of the medium radio waves used all lie within the limits of 2·990 and $2·995 \times 10^{10}$ cm./sec. for transmission over a clear air path, or over sea or fresh water. As these limits are within the accuracy of the measurements, no definite conclusions can be drawn as to the effect of a salt- or freshwater path on the velocity of propagation. In the case of transmission overland, a somewhat lower value of $2·950 \times 10^{10}$ cm./sec. was obtained, although this would appear to be subject to some uncertainty in determining the true path of transmission, due to various intervening obstacles.

Thus it is found that for the radio-frequency portion of the spectrum, the methods so far used for the determination of the velocity are much less accurate than those used for the velocity of light; and it may be stated that within the limits of the experimental accuracy so far attained, which is not better than 0·1 per cent, the velocity of propagation of medium radio waves is about $2·990 \times 10^{10}$ cm./sec. The experimental evidence so far available indicates that this value for the velocity is the same for all radio wave-lengths within the accuracy specified above. There is some evidence that the phase velocity may be reduced below this value near the transmitting aerial, and it may also be modified when transmission takes place close to the surface of the earth; but it seems doubtful if this variation from the free space value amounts to more than the experimental accuracy, except where obstacles such as trees and mountains intervene in the path of propagation. In this case it is not necessarily the velocity which has altered, but rather that the path traversed has been increased.

This discussion of our present knowledge leaves the problem of the measurement or calculation of the actual time of transit of radio waves between sender and receiver still open to investigation. This type of information may be required for a number of purposes, such as the use of time signals for the comparison of chronological standards and for the determination of differences of longitude. For the solution of this problem, a knowledge of the free space speed is only one requirement: it still needs a precise specification of the actual path, rectilinear or otherwise, followed by the waves, and of any modification to the velocity value produced by atmospheric or ionospheric conditions.

MICROBIAL FACTORS IN THE DIGESTIVE ASSIMILATION OF STARCH AND CELLULOSE IN HERBIVORA

By FRANK BAKER
County Technical College, Guildford

MICROBIAL processes are directly concerned in the digestive assimilation by Herbivora of the starch and crude fibre components of their diet. In ruminants the rumen and in non-ruminants the cæcum is the chief focus of these activities. Great diversity of opinion, however, exists in regard to the type or types of micro-organisms primarily responsible for the changes taking place[1,2]. This confusion must in large measure be attributed to the application of methods inappropriate to the resolution of the problem; and in particular to the exclusive and premature reliance placed on pure cultural technique. For, first, it is impossible by plating out to distinguish with certainty between the casual passengers through and the permanent inhabitants of the gastro-intestinal tract. Secondly, the majority of micro-organisms indigenous to the cæcum and rumen are not susceptible of cultivation on any of the media ordinarily employed.

I have shown, however, that these difficulties can be circumvented by the use of methods of direct microscopical observation[3]. It must be emphasized that these methods are not confined to a mere academic enumeration of species. By examination in polarized light[3,4,5,6] the disintegration of cellulosic structures can be studied in detail from start to finish in material freshly withdrawn from the rumen or cæcum. The changes taking place can be still further elucidated by histochemical and staining procedures[4,5,7]. Similar methods can be applied to the study of starch granules in process of disintegration. Thus the functional activities as well as the morphological characteristics of the micro-organisms present may be ascertained. The results obtained can be recorded by photomicrographs. Nor, again, is the method of direct microscopical observation limited to qualitative data. Ferber long ago showed that the influence of dietetic factors on the rate of multiplication of the rumen Protozoa could be studied by the use of counting methods[8,1]. In collaboration with the Hannah Dairy Research Institute I have since found that similar methods can be extended to the iodophile microflora of the rumen and cæcum. Lastly, it may be noted that the method may be applied to formalized samples, so that material may be preserved *in vitro* for an indefinite period. This makes it possible to check or amplify observations over the entire course of a lengthy investigation. Similarly, by the use of coded samples, the objectivity of the data obtained by counting methods can be placed beyond question and subjective influences eliminated.

It is clear, therefore, that by the systematic assemblage and examination of appropriate collections of material a whole field of research is opened up which lies altogether beyond the range of pure cultural methods of investigation. These possibilities will, however, only be realized to the full when the method of direct microscopic examination has been adopted as a routine procedure by a sufficient number of observers. Nevertheless, observations accumulated over the course of several years already make it possible to elucidate some of the more conspicuous features which attend the microbial decomposition of starch and cellulose in Herbivora. The purpose of this article is to outline a consistent picture of these features and tentatively to indicate their significance in regard to the digestive process of the host-animals. To this end it is necessary briefly to summarize the general characteristics of the microbial associations established in the rumen or cæcum. These associations include, in addition to a number of species with which we need not here concern ourselves,[4,5,9]:

(*a*) *Iodophile micro-organisms* of taxonomically diverse types such as collectively constitute the *iodophile microflora*[9];

(*b*) Protozoa belonging to a highly specialized order of ciliates, the Entodiniomorpha[11].

Both these groups play a part in the carbohydrate transformations of the gastro-intestinal tract. The distinctive feature of the iodophile micro-organisms is the blue-black reaction which they give with iodine, owing to the deposition within them of a polysaccharide[12], the so-called bacterial starch or granulose. Most of the species encountered are of unusually large dimensions[4,5,7,9,10,13]. They include sarcina[5,13], Diplococcus[7], Streptococcus[4,5,7,9,13], Spirillum[5,13], and Clostridial forms[10], together with sporing and non-sporing rods[7,9,10] and several species of uncertain systematic position[5,13]. In addition, organisms of Oscillarian affinities are encountered in the guinea pig, sheep and cow[9,12,13].

The iodophile microflora becomes established in the rabbit towards the close of milk feeding with the adoption of a vegetable diet[14]. Different constellations of species may be present in different species of Herbivora. Where these differences are marked, as in the case of the guinea pig and rabbit, they may persist even when the animals are fed on the same diet and kept in the same cage. Thus internal as well as external factors determined the characteristics of the microflora.

That certain iodophile species play a determinate role in the decomposition of cellulose can be demonstrated by direct microscopic examination in polarized light[6]. The iodophile micro-organisms are encountered upon the surfaces and within the interstices of the vegetable fragments present. Disintegration is accompanied by excision of enzymatic cavities, the contour of which corresponds precisely with that of the micro-organisms by which they are produced. In the affected regions birefringence ceases and microchemical reactions disappear. Lignified structures partially and cutinized structures entirely resist disintegration. The age, therefore, as well as the botanical species of the plant material fed will affect the amount of cellulose digested[3].

Examination of rumen or cæcal contents demonstrates that iodophile micro-organisms are also directly concerned in the decomposition of starch.

Granules in all stages of disintegration are encountered upon the surfaces of which innumerable iodophile micro-organisms are lodged. Streptococci are the species normally associated with this process in the rumen of the sheep and cow and in the cæcum of the rabbit. In the guinea pig curved iodophile clostridia are the predominating type. Granules undergoing disintegration show a progressive diminution in birefringence. Their originally blue-black is gradually replaced by a reddish reaction to iodine. In non-ruminants, such as the guinea pig, I have observed that the feeding of a diet rich in starch results in a very marked increase in the total iodophile microflora of the cæcum. This increase involves the free-living species as well as those attached to the disintegrating granules. Again, in collaboration with the Hannah Dairy Research Institute, I have established, by counting methods, that the addition of increasing amounts of starch to rumen contents incubated *in vitro* results in a parallel increase in the rate of multiplication of iodophile micro-organisms of all types. These facts demonstrate that the ability to synthesize iodophile polysaccharide is not confined to the particular species directly responsible for disintegration. Similar conclusions may legitimately be extended to the decomposition of cellulose. The view may therefore be advanced that the iodophile microflora not only comprises the particular agents immediately concerned in the disintegration of starch and cellulosic substrates but, in addition, functions as a general acceptor of the soluble products of decomposition liberated[3, 4, 5, 7]. In this way such products are removed from further participation in the reactions taking place and a storage of carbohydrate thereby temporarily effected.

The activities of the iodophile micro-organisms may be supplemented by those of the Entodiniomorpha with which, in some herbivorous species, they are associated. Ciliates of this kind, which are absent from the cæcum of such non-ruminants as the guinea pig and rabbit, are present in enormous numbers in the rumen of most ruminants. Trier[15] long ago demonstrated that they are able to ingest and digest starch grains. Assimilation is accompanied by the deposition of abundant reserves of paraglycogen[15, 16]. In addition to starch, cell-wall residues are ingested. This fact has led some observers to attribute to the ciliates an important role in the digestion of cellulose. Comparisons have been made with the activities of the polymastigotes[17] of lignophagous termites. I have shown that the grounds advanced for these comparisons are not valid[5]. Even, moreover, were the supposed capacity of the rumen Protozoa to digest cellulose demonstrated, it would be of trivial functional significance to the host animal, since the size of the majority of vegetable fragments initially present is such as absolutely to preclude ingestion. But in fact, wherever, as is often the case, ingested particles show signs of disintegration, this can always be referred to the action previously exerted upon them by iodophile micro-organisms. Thus the activities of ciliates are of a subordinate kind in comparison to those of the iodophile microflora, and constitute an orbital fringe to the focus of carbohydrate transformations occurring in the rumen.

In the meantime it will be clear that, irrespective of specific peculiarities, the microbial associations of the herbivora are organized[3, 4, 5, 7] in such a way as directly to secure the accumulation, as products of microbial synthesis, of the substances (other than waste gases) initially liberated in the process of decomposition. The conclusion has therefore been provisionally drawn that it is the substances synthesized, such as microbial protein and polysaccharide, rather than the initial products of decomposition, such as organic acids, that are utilized by the host animal. For this to be possible, it is necessary that at some subsequent period they should be liberated in an assimilable form. In conformance with this requirement is the fact that, in both ruminant and non-ruminant herbivora, an enormous reduction in the iodophile microflora has taken place by the time the food residues have reached the lower regions of the large bowel. I have determined by counting methods that, in the rabbit, this reduction can amount, at a low estimate, to two thirds of the micro-organisms present in the cæcum. The factors concerned in this elimination have been investigated[14] and include:

(1) Ingestion and digestion by ciliates;
(2) Action of digestive enzymes;
(3) Bacterial autolysis.

In the simplest example, elimination may be effected by autolysis alone. This is the case in the rabbit and guinea pig, where Entodiniomorpha are absent and the position of the cæcum precludes an intensive action of digestive enzymes. In ruminants autolysis is reinforced by the activities of the rumen Protozoa. Free-living iodophile micro-organisms, in addition to those adherent to starch grains and vegetable fragments, are taken in and afterwards assimilated. The ciliates in turn are digested in the abomasum. Thus a proportion of the bacterial protein and iodophile polysaccharide present is continuously converted into protozoan protein and paraglycogen. Since it can be demonstrated[14] that the Protozoa are far more readily accessible to the action of digestive enzymes than the iodophile microflora, the possible physiological significance of this conversion cannot be overlooked. In any event it is evident that, in consequence both of the presence of ciliates and of the anatomical relationships of the rumen, not only the process of microbial decomposition and synthesis but also the mechanism of elimination achieves a higher level of organization in ruminant than in non-ruminant Herbivora[3]. This functional differentiation will tend to procure a greater efficiency and an increased latitude of readjustment for the microbial process. To it may in part be due the superior capacity shown by ruminants in the assimilation of crude fibre diet components, and perhaps also their ability to utilize protein substitutes.

In this last connexion it is noteworthy that Westphal was able to maintain the rumen Protozoa for five weeks *in vitro*, in a rumen liquor, by daily addition of small quantities of starch and urea[16]. Ancillary observations show that an iodophile microflora was established in his cultures. In advance of more detailed investigations, the attempt would be premature finally to assess the significance of Westphal's results. Sufficient data have, however, in the meantime been adduced to show that the actual mode of transference to the tissues of the animal of the polysaccharides present in the vegetable materials ingested devolves, *inter alia*, upon the character of the microbial association established in the gastro-intestinal tract. The comparative investigation of such associations, by methods of direct microscopical observation, opens up a hitherto unexplored field for inquiry. By the use of fistular animals the effects of diet upon the microbiological equilibria established can be ascertained. These influences can be still further elucidated by *in vitro* incubations.

Finally, by the enclosure of material in sacs, following the ingenious procedures elaborated by Dr. McAnally at Cambridge[18], it should be possible to investigate the character of the microbial process associated with the decomposition of individual species of food plant. Information assembled in this way, in addition to its theoretical interest, would have a direct practical bearing upon the complex problems which arise in connexion with the effective utilization of particular diets and with the elucidation of an economic feeding practice.

THE CONDITION OF FRESHLY BURNT GASES

By DR. A. G. GAYDON

Imperial College of Science and Technology, London

WHEN inflammable gases are exploded with air or oxygen, the products are frequently observed to luminesce after the passage of the main flame front; the effect is especially marked with explosions in closed vessels, the burnt gases glowing brightly as the pressure waves caused by the explosion travel back through them. In one series of experiments with carbon monoxide, David found that this 'afterburning' could be seen for so long as 14 sec. Observations of this type, and measurements of the temperature distribution following explosions in closed vessels, led Ellis, Wheeler and Morgan to support this afterburning concept. David and colleagues took a series of time-pressure records for explosions of mixtures of dry carbon monoxide and air with small amounts of hydrogen added, using vessels of various dimensions; they found that the ratio of final to initial pressure was greater for explosions in large vessels than in small vessels, from which they concluded that combustion was incomplete in the smaller vessels, and therefore probably still incomplete even in the larger vessels.

Lewis and von Elbe[1] have made a detailed criticism of these conclusions, attributing Ellis, Wheeler and Morgan's observations to necessary results of the temperature and pressure changes taking place following an explosion in a closed vessel, and suggest that David, Brown and El Din's results were caused by pockets of unburnt gases. David has since confirmed the earlier results using explosion vessels of modified design to eliminate any pockets of unburnt gas. Lewis and von Elbe support their conclusion that afterburning is not a real phenomenon by experiments with ozone and with mixtures of hydrogen and oxygen, the maximum pressures attained and the temperature gradients set up agreeing with those expected theoretically.

While the existence of a true afterburning for fuels rich in hydrogen remains in dispute, there can be no doubt from the well-known experiments of the late Prof. W. A. Bone on the marked catalytic action of moisture on the combustion of carbon monoxide that, for very dry gases, explosions are only induced with powerful igniting sparks, and the resulting explosions are of long duration and leave a considerable amount of unburnt gases. Garner and colleagues have studied, qualitatively and quantitatively, the infra-red radiation from explosion flames of carbon monoxide – oxygen mixtures in various states of dryness, and in the presence of certain catalysts. The infra-red radiation is much greater from the carefully dried mixtures, and is considerably reduced by small traces of certain catalysts such as ethyl nitrate or hydrogen. From these experiments, Garner, Hall and Harvey[2] concluded that the carbon dioxide molecules contained initially a considerable excess of vibrational energy, this amounting in some cases to as much as 24 per cent of the heat of combustion.

In addition to the experiments on explosion flames, David has found evidence for the existence of considerable amounts of latent energy in stationary flames, the observed maximum flame temperatures being less than the calculated values. Again, the subject has aroused considerable controversy between Lewis and von Elbe and David, and again it seems difficult to express a final conclusion about the reality of this latent energy for fuels rich in hydrogen, but it is certain that there is a real discrepancy between the observed and calculated temperatures for flames of dry carbon monoxide, this discrepancy being reduced by the addition of a little water or hydrogen to the flame. Measurements of the temperature of dry carbon monoxide – air explosions using thermocouples of bare wire, and of quartz-coated wire, show a very big difference ($\sim$ 300° C.) for weak mixtures, but little difference for mixtures rich in carbon monoxide; this appears to indicate that there is considerable abnormal dissociation of the carbon dioxide molecules in such flames.

Following the observation, by Fowler and Gaydon, of the afterglow of carbon dioxide in a discharge tube, David postulated the existence of carbon dioxide molecules of abnormal structure (electronically activated) to account for his experiments on afterburning and latent energy, and he has recently[3] defended this postulate against the views put forward by Gaydon[4], which attempt to explain the afterburning of carbon monoxide as due to delay in the equipartition of vibrational energy.

From a study of the spectrum of the carbon monoxide flame, Gaydon concluded that the emitter of the spectrum was carbon dioxide, and that emission corresponded to transitions from the electronic state responsible for the weak absorption by carbon dioxide below 1700 A., to the ground state. It has been suggested that the upper state may not be linear as is the ground state of carbon dioxide; this would account for the difference between the regions of absorption and emission for this system, and it would then follow, from the Franck-Condon principle, that in emission transitions would only occur to high vibrational levels of the ground state. Since the normal carbon dioxide molecule is in a $^1\Sigma$ state, it cannot be formed from normal CO($^1\Sigma$) and normal oxygen O(^3P); thus in the combustion an electronic rearrangement must take place at some stage, the most likely stage being after the formation of the carbon dioxide molecules. The electronic transition may take place either freely by radiation, or on collision, but in either case will leave the carbon dioxide molecules in the ground electronic state with excess vibrational energy. It is these vibrationally activated molecules which are believed to be responsible for the afterburning. It has been shown from consideration of supersonic dispersion in pure carbon dioxide and from calculations of radiative life-times that these activated molecules may persist for an appreciable fraction of a second; moreover, the presence of such activated molecules will lead to abnormal dissociation. This concept of vibrationally activated carbon dioxide molecules agrees with Garner's conclusions from measurements of infra-red radiation, and is particularly successful in explaining the failure to observe the band at 14·9 μ in emission. The marked catalytic action of water in promoting the combustion and reducing the infra-red emission from burning carbon monoxide readily falls into line on this theory, as it is known from supersonic measurements that water molecules are extremely effective in deactivating vibrating carbon dioxide molecules.

Quantitative objections to David's original hypothesis of electronically activated carbon dioxide and water molecules were pointed out by Egerton and Ubbelohde[5] at the time of announcement, it being stressed that the amount of radiation emitted was insufficient to account for the large amount of latent energy reported. Gaydon has since pointed out that as carbon dioxide, even in the liquid state, is quite transparent throughout the visible and quartz ultra-violet regions of the spectrum, there cannot well be any low-lying electronic states of carbon dioxide to account for the latent energy. If an electronic state of high energy is involved, then Egerton and Ubbelohde's arguments must hold, and also the afterburning gases would be expected to show properties even more remarkable than those of active nitrogen. The hypothesis of vibrationally activated molecules seems also to be more successful in explaining the abnormal dissociation, the effect of pressure waves in causing the afterburning gases to luminesce brightly, and the failure to observe the 14·9 μ band of carbon dioxide in emission from explosion flames, than does the hypothesis of electronically activated molecules. It must be pointed out that David[3] speaks of the radiation from afterburning gases being emitted during a *collision*; the spectrum of the carbon monoxide flame shows that the radiation has a discrete structure and must therefore be emitted by a molecule in a quantized energy state, not by a collision. David also speaks of observations by Kitagawa and by Gaydon of the emission spectrum of activated water molecules in flames; this is true; the analysis shows, however, that the water molecules are *vibrationally* activated. No stable electronic state of the water molecule which could possibly account for the latent energy is known. Although the vibration-rotation spectrum of water is strongly emitted by the hydrogen flame, it is probable that in this case the emission is thermal in origin; there does not appear to be any evidence to indicate that vibrating water molecules have an abnormally long life, and it is unlikely that they contribute appreciably to any afterburning.

A discussion of the afterburning problem also raises the fundamental question as to whether or not pure gases luminesce when heated to temperatures as high as those produced in explosion flames. If, as is frequently stated, hot gases do not radiate, then the case for the existence of some form of afterburning is proved without more ado, because there can be no doubt that under some conditions freshly burnt gases do continue to luminesce, and if this luminescence is not thermal in origin, it must be due either to continued combustion or to some form of activated molecule. Lewis and von Elbe have expressed doubts as to whether the common assumption that hot gases do not luminesce is really correct, and Gaydon retained an open mind, merely recording[6] that he was unaware of any experiments at sufficiently high temperatures. It must be remembered that in closed-vessel explosions sound, or even shock, waves caused by the explosion may produce momentary local heating considerably above the theoretical maximum temperature, and that such experiments as those of Pringsheim do not cover these very high temperatures. For the permanent gases, nitrogen, oxygen and carbon monoxide, there is little reason to expect luminescence at the temperatures attained in ordinary gas explosions, but for carbon dioxide there will certainly be some dissociation at high temperatures, and there would not appear to be any real distinction between the recombination following this dissociation and normal combustion, so that emission of the type found during the combustion might be expected when carbon dioxide is strongly heated.

Nevertheless, the quantitative measurements of the amount of radiation from the carbon monoxide flame made by Kondratjew show clearly that the visible radiation from this flame is a result of the chemical action and is not purely thermal, and this is supported by the observation of a cool flame for carbon monoxide, the emission spectrum of which has recently been found by Gaydon to be similar to that of the normal flame. Since the bulk of the emission from the ordinary flame is due to chemical and not to thermal causes, there seems little doubt that in the observed cases of afterburning the emission is also the result of chemical action rather than mere heating effects. This is supported by David's recent note[7], in which he stresses that the intensity of the afterburning depends on the condition of the gases and not solely on temperature. Also, spectrograms of afterburning gases in the internal combustion engine[8] show almost complete identity with the ordinary flame spectrum of moist carbon monoxide *including the presence of the OH bands*; the identity of these spectra would appear to support the view that the afterburning is really due to continued burning rather than to thermal emission or to emission from electronically activated molecules.

The determination of latent energy in flames also involves the difficult problem of measuring flame temperatures accurately. The two most favoured methods are the sodium line reversal method and platinum resistance thermometry. The sodium line reversal method has been severely criticized by David, and recent developments seem to show that this criticism is justified; it is known that the reaction

$$H + H + Na = H_2 + Na^*$$

may result in unduly strong emission from the hydrogen flame, and it has now been found that strong emission of the sodium lines occurs in the cool flame of carbon monoxide at temperatures around 600° C., so that in the combustion of carbon monoxide it is also probable that the excitation of the lines is chemical rather than thermal. Lewis and von Elbe have, in turn, criticized David's use of the platinum resistance thermometer, saying that insufficient allowance was made for radiation losses. Radiation losses can, of course, be compensated for, but another possible objection is that catalytic action at the surface of the wire (compare the action of palladium in promoting surface combustion) may cause the wire to record too high a temperature; actually the platinum resistance wire usually gives lower temperatures than the sodium line reversal method, and is probably the more reliable if due care is taken to compensate for heat losses. While the exact amount of latent energy in flames may remain in doubt, the definite rise in temperature of dry carbon monoxide flames when a trace of moisture or hydrogen is added shows that for carbon monoxide, at least, there is some latent energy.

It should be stressed that the semi-quantitative development of the concept of vibrationally activated carbon dioxide molecules is successful in explaining the abnormal dissociation and therefore the afterburning of dry carbon monoxide, but that for fuels rich in hydrogen it seems unlikely that it could account quantitatively for any afterburning or latent energy of long duration, although it may still explain such effects if of much shorter duration (perhaps less than 0·1 sec.).

Apart from the afterburning, 'live' flame gases show other very marked properties that are not common to mere hot gases. Experiments by Egerton and Gaydon show that they are more highly ionized, and appear to possess the property of igniting other combustible mixtures. Spectra of afterburning gases show the presence of OH radicals. It is known[9] that under discharge tube conditions OH radicals have a life of at least 0·4 sec. At atmospheric pressure their life will presumably be much shorter, but the persistence of a trace of these radicals might account for some of the peculiarities of 'live' exhaust gases. It has also been found spectroscopically that if flame gases are chilled by contact with cool metal surfaces, either peroxides or HCO radicals are carried through in the products. At the temperature of the freshly burnt gases, these reactive constituents may continue o react with any excess oxygen and may, as in certain cool flames, maintain chemically a small concentraion of highly activated molecules.

It may be concluded that the afterburning and other peculiarities of the combustion of dry carbon monoxide are best explained in terms of vibrationally activated molecules, and cannot well be due to carbon dioxide molecules of abnormal structure (electronically activated). Similar afterburning and latent energy in the combustion of ordinary fuels, if of short duration, might be due to the same cause, but any such ffect of long duration would require an alternative xplanation. The persistence of radicals and reactive ntermediary products of the combustion may exlain some of the abnormalities of 'live' flame gases.

GALILEO, NEWTON AND HALLEY

ON Friday, October 9, the Royal Astronomical Society held a meeting at its premises in Burlington House in celebration of the tercentenary of the death of Galileo Galilei (1564–1642) and the birth of Isaac Newton (1642–1727) and the bicentenary of the death of Edmond Halley (1656–1742). An exhibition of portraits and other memorials of the three astronomers, collected from various sources and arranged in the Grove-Hills Library, aroused considerable interest, after which a large gathering, presided over by the president of the Society, Prof. S. Chapman, and including representatives of the Royal Society, the Royal Academy, the Royal Institution, the Royal Geographical Society, the Royal Meteorological Society, the Physical Society, the Imperial College of Science and Technology, the Science Museum, the British Astronomical Association, the British Council, the Fighting French and other bodies, assembled in the meeting-room.

The proceedings opened appropriately with a short account by Mrs. M. E. Evershed of the lives and outstanding characteristics of Galileo, Newton and Halley, and this formed a fitting introduction to papers on their scientific achievements by Prof. H. Dingle, Prof. H. C. Plummer, and the Astronomer Royal, Dr. H. Spencer Jones. The contrast in character of the three men was well brought out by Mrs. Evershed—Galileo intensely alive, active and eager, Newton reserved and difficult to understand, and Halley sociable and friendly, with a sunny, open nature.

Prof. Dingle summarized Galileo's chief contributions to modern thought—which takes its form mainly from his work—under three headings. First, Galileo originated the scientific method as a definite, consciously adopted, philosophical procedure. He was the first to make it his specific aim to discover how things worked and not why they worked so. This followed from his new view of the works of Nature as objective existences which man was able, though not without great pains, to understand, instead of as instruments designed to meet man's requirements. Galileo's destruction of the anthropocentric system of philosophy was more vital for subsequent thought than Copernicus's destruction of the geocentric system of astronomy.

Secondly, having prepared the ground for science, he laid its foundations and began the building. He made possible the mathematical study of motion by representing time as a measurable geometrical extension, and himself made considerable progress in that study. He arrived at what we call Newton's First Law of Motion; realized the significance of inertia; showed that falling bodies, whatever their weight, exhibit the same uniform acceleration, and that projectiles describe parabolas; went a long way towards the formulation of Newton's Second Law of Motion and the discovery of the calculus, which, in fact, he actually used; and stated clearly the principle of relativity, which Einstein had to restore in 1905 after unwarranted violation.

Thirdly, Galileo's contributions to pure astronomy consisted, first, in the establishment of the general principle of the uniformity of Nature by the abolition of the supposed distinction between the perfect heavens and the imperfect earth, and next in the independent invention of the telescope and the enlargement of the field of possible knowledge by a greater factor than that achieved by any man before or since. With an instrument vastly inferior to even the most modest of present-day telescopes, he discovered the irregularity of the surface of the moon, the multitude of the fixed stars, the stellar character of the Milky Way and of some 'nebulæ', the four great satellites of Jupiter, sunspots and the sun's rotation, the phases of Venus, the abnormality of Saturn, and the cause of the 'secondary light' (earthshine) on the moon.

As a writer, Galileo's chief characteristic was his almost complete modernity. He thought and expressed himself in a manner which makes an instant appeal to us of the present day and stands in striking contrast to the medieval style of Kepler, who was, in fact, his contemporary. But while he opened his mind with perfect candour, he rarely showed the feelings with which, for the first time in history, he saw a new universe unrevealed to the naked eye.

Prof. Plummer, in a wide survey of Newton's various activities, stated that his religious life was normal and characteristic of a man of the seventeenth century ; it must not be judged from a modern point of view. What was curious was that that view was the result largely of the success which had attended the Newtonian system of natural philosophy. It was an undesigned effect not contemplated by Newton, but the cruder form of scientific determinism was reached as early as the eighteenth century, and its extreme exponent was probably to be found in Laplace.

Newton's removal to the Mint in later years may have represented a loss to science, but that should not cause the importance of his work there to be underestimated. It was required at a time of crisis in the financial history of Britain, and his work was carried out efficiently, honestly and expeditiously.

Newton gave much time to chemistry, but the results proved sterile. In physics it was otherwise, and the subjects of heat and electricity bore the impress of his work. But it was in optics that Newton not only made important and famous contributions, but also exercised the greatest influence on subsequent developments. This influence was not altogether fortunate. There is much that is suggestive and subtle in his views, but the fact remains that his authority was long quoted against the undulatory theory, and was therefore detrimental to a necessary stage in the progress of optical development.

The mathematical achievements of Newton were undeniably great. Owing to late publication they cannot be said to have influenced contemporary progress as they should have done, and even to-day it is doubtful if they are generally appreciated as they deserve to be. It is therefore pleasanter to dwell on the "Principia" and to see in it the true monument of Newton's greatness as well as the triumphant culmination of the story which began with Kepler's "Astronomia Nova" in 1609 and the work of Galileo collected in the "Discorsi" of 1638, and follow these two lines through Horrocks in celestial mechanics and Huygens in dynamics. There was much to be done to advance from the undergraduate ideas conceived at Woolsthorpe before the riddle of the universe could be solved, and it was not accomplished by one man alone. But when the answer came, it was so complete in its development that without Newton a long delay would have been inevitable, for the "Principia" not only revealed the law of gravitation, but also taught how it was to be applied.

The Astronomer Royal directed attention first of all to Halley's great versatility. He was at once mathematician, astronomer, physicist and statistician ; geographer, hydrographer and geomagnetician ; navigator, practical seaman and the first scientific voyager ; scholar, diplomat and man of affairs ; and in every branch of knowledge that he cultivated he achieved distinction. His favourite pursuit, however, was astronomy, to which he decided to devote himself at the age of sixteen. In 1676, when he was twenty years old, he set sail for St. Helena, where he remained for a year for the purpose of determining the positions of the southern stars, which had not up to then been properly observed.

Halley's greatest service to human knowledge, however, was the share that he took in bringing Newton's "Principia" before the world. As de Morgan has said, "but for him, in all human probability, that work would not have been thought of, nor when thought of written, nor when written printed". Having extracted from Newton a determination of the law of force (the inverse square law) under which planets move in elliptical orbits with the sun in a focus, he realized better than anyone else the importance of the matter, and persuaded Newton to develop his results and to communicate them to the Royal Society, of which Halley had been appointed clerk. The Society decided to print the work (the first book of the "Principia"), but found itself without funds, whereupon Halley undertook to defray the cost himself. The second and third books were presented later, and Halley again rendered a great service by persuading Newton to abandon his intention of withdrawing the latter.

Newton's work was followed up by Halley himself, first by directing attention to the effect of the mutua gravitational attraction of the planets on their motions, but chiefly by his investigations of the orbits of comets. He collected all available observations ; devised an arithmetical calculus for computing the orbits, and provided tables for facilitating the computations ; and made the first definite prediction from Newton's law of gravitation by his prophec that the comet now known by his name would appea again in 1758.

Halley next turned his attention to the neglected field of Greek geometry, in which he did valuable work and to the problems of the earth's magnetism. Thi led to his being given a commission in the Roya Navy, in charge of His Majesty's Pink, *The Paramour* He made several voyages, as a result of which h published charts of the variation of the compass ove the Atlantic Ocean and over the whole world, show in the now universally used form of isogonal lines and made a survey of the tides in the English Channel

Halley was the first to point out the possibility o determining the sun's parallax accurately fron observations of the transit of Venus, and his effort led to expeditions being sent out to observe th transits of 1761 and 1769. He was also the discovere of the proper motions of stars. In 1720, at the ag of sixty-four years, he succeeded Flamsteed a Astronomer Royal, and turned his chief attention t the improvement of the current tables of the moon for the purpose of determining longitudes by th method of lunar distances.

Halley was a man of genial disposition, quick an vivacious, with a keen humour and a gift for friend ship. In commemorating the bicentenary of Halley' death, it is appropriate to recall the conclusion of th Latin inscription on his tomb, which in translatio reads : "As when living, he was so highly esteemed b his countrymen, gratitude requires that his memor should be respected by posterity."

OBITUARIES

Prof. G. G. Henderson, F.R.S.

George Gerald Henderson was born at Glasgow on January 30, 1862. After preliminary education at a private school he proceeded to the University of Glasgow where, taking up the study of chemistry, he graduated B.Sc. in 1881 and later on took also an honours degree in arts. He spent in addition some time in Leipzig studying chemistry with Johannes Wislicenus. In 1884 he joined the staff of the Chemistry Department at the University of Glasgow under Prof. John Ferguson, and about the same time he became secretary to the Glasgow Section of the Society of Chemical Industry, carrying out the duties of the post with great acceptance until 1893, thus beginning a connexion with that body which became closer and closer to the end of his life.

In 1889 he became lecturer in chemistry at Queen Margaret College, the women's branch of the University, where he had practically an independent department. In 1892 he was appointed to succeed Prof. William Dittmar in the Freeland chair of chemistry at the Andersonian College, and in his twenty-seven years in this post he did the chief part of his lifework. At the time of his appointment the laboratories and equipment were very archaic, and he had to work in these adverse conditions for a good many years. In 1901, however, the fine new buildings of the Royal Technical College were commenced and in 1905 they were completed, Henderson having given much time and thought to their planning and equipment. Some ten years later he was active in a consultative capacity when, in 1913, the affiliation of the Royal Technical College with the University in respect to engineering and other applied subjects was carried through.

During all these years Henderson was steadily developing his department, and especially instilling an appreciation of research work in chemistry into a considerable number of senior students. Henderson being an all-round man, his work was on various subjects. It included the investigation of salts of some hydroxy acids, action of ammonia on metals at high temperatures with the late (Sir) George Beilby, molybdenum and tungsten derivatives of lactic acid, etc., but his work tended more and more in the direction of terpene chemistry; to investigation of the action of chromium oxychloride, hypochlorous acid and hydrogen peroxide on camphene, pinene, bornylene and limonene, with the relationship of borneol and isoborneol and of camphene and bornylene, and other similar problems. It is with this that his name s most likely to be associated in the future. In it he has had many collaborators, who are carrying the work begun with him to further stages.

During 1914–15 he was president of the Society of Chemical Industry; in 1916 he was elected a fellow of the Royal Society, and he was also in that year president of Section B of the British Association; in 919 he was appointed to the regius professorship of hemistry in the University of Glasgow. There he had under his own particular charge the junior and he senior inorganic work, but he carried on as well, with various assistants, his investigations on terpenes nd other subjects. He devoted himself, at the University, with great assiduity to the routine of his department, and played a very active and useful part on the business side of University affairs in many capacities. He was dean of the Faculty of Science for three years, member of the Library Committee for three years, and for eight years, from 1925 until 1933, he was a member of the University Court. He also planned with the architect the major part of the new chemistry buildings. It is clear from his career that he has always been regarded by others as a man of affairs whose wise counsel was held in high esteem.

While at Glasgow he was president of the Institute of Chemistry during 1924–27 and president of the Chemical Society during 1931–33. At seventy years of age the railway travel which the last office entailed meant for one, even of his robust constitution, a considerable strain. In 1937 there came to him, as a peculiarly fitting tribute at the end of a long and active life spent in promoting chemistry and chemical industry, the award of the Medal of the Society of Chemical Industry, a recognition conferred in alternate years for "conspicuous service rendered to applied Chemistry by research, discovery, invention, or improvements in processes".

Henderson was so well known that anything about his personality may seem superfluous, but for those who had not met him it may be said that he was of full middle height, spare of form, with brown moustache which never altered its shape in obedience to the dictates of fashion. In fact, Henderson was one of the most unchangeable of men. He always smoked the same kind of pipe and the same kind of tobacco; he always wore the same kind of eye-glasses—no tortoiseshells for him; always the same type of clothing, well tailored, rich not gaudy; and he had the kind of figure that a tailor must rejoice in. The writer was one of the students at the old Andersonian College on the day that Henderson was inducted to his new charge, and it is hardly any exaggeration to say that since then he had altered not at all when he took his last farewell of us in 1937.

He had a rather deliberate manner of speech which, in most anecdotes, crystallized into "Ah, yes", and it often helped to make his replies effective; he was not easily taken at a disadvantage. Once during the big strike of 1926 he came into the writer's room and mentioned casually that he had just been interviewed by a student who had started the conversation by explaining, in very truculent fashion, that his father was a working-man. "Ah," said G. G., "I'm very glad to hear that. So was mine!"

He had decided to retire at the end of September 1937 and he looked forward to a peaceful time at Horsaclett, the house he had bought some years previously near Tarbert, Harris, and where he indulged himself in what was certainly his chief sporting interest, fishing. Mrs. Henderson (his cousin Agnes Mackenzie Kerr whom he had married in 1895 and whom everyone who knew her remembers with pleasure) went north in early summer, as she usually did, to get things ready, but shortly after arrival at Tarbert she died suddenly of heart failure. Thus, just on the threshold of the quiet companionship they had looked forward to, and which indeed had always been their ideal, his hopes were utterly dashed. It was a stunning blow which Henderson bore with stoical fortitude. He had never been accustomed to wear his heart upon his sleeve, and he did not do so then, but the rest of his life can have been little more than patient endurance. Outwardly, however, he remained what he had always been until about the middle of last June, when he rather suddenly became ill and was removed to hospital with the prospect of an operation. This could not be fully performed, and, back in his home, he gradually sank, clear in mind while slowly wasting away, until the end came on September 28. In unostentatious fashion he had lived an active, useful life, and he will be remembered with gratitude and affection by many old students and colleagues, the world over. He died in surroundings very dear to him, and there he now rests beside his beloved companion of more than forty years.

T. S. PATTERSON.

Prof. H. D. Wright

THE death of Hedley Duncan Wright at his home in Liverpool, on September 9 at the early age of fifty-one, has deprived bacteriology prematurely of one of its most distinguished and indefatigable workers.

Wright was born at Ulverstone, Tasmania, on March 3, 1891. He arrived in Great Britain in 1910 to read medicine at the University of Edinburgh after taking his B.A. in classics at the University of Tasmania. While still a student he served as a dresser in the Scottish Red Cross Unit in Serbia during the second Balkan War. In 1916 he graduated in medicine with first class honours and immediately joined the R.A.M.C., in which he held a commission until 1920. He saw active service in France, India and East Persia. His first appointment after demobilization was as lecturer in bacteriology at Edinburgh under his old professor (James Ritchie). During 1921–23 he was the assistant superintendent of the research laboratory of the Royal College of Physicians, Edinburgh, where he obtained valuable experience in statistical methods from the director, A. G. Kendrick, later to be of great value to him in his research work.

In 1923 Wright was appointed lecturer in bacteriology at University College Hospital, London, becoming University reader in 1928. It was here, working under A. E. Boycott, that he first embarked on those studies in clinical bacteriology, notably subacute infective endocarditis and pneumococcal septicæmia, which first directed the attention of his colleagues to his outstanding ability. The submission of a thesis on this work, which has since become classical, earned for him in 1925 the Edinburgh M.D., with gold medal, and the D.Sc. followed in 1927. In 1930 he became the first holder of the newly created chair of bacteriology in the University of Sydney, where he remained for four years. In 1934 he was invited to succeed J. M. Beattie as professor of bacteriology in the University of Liverpool and bacteriologist to the Port and City of Liverpool.

In addition to these academic posts, the recognition of Wright as an eminent authority on his subject led to his appointment in 1937 to the Bacteriological Committee of the Medical Research Council, where his wide personal experience and deep knowledge of the literature were often of great assistance; in 1939 he served on the Council's sub-committees on cross-infection in hospitals and on diphtheria immunization. He joined the Pathological Society of Great Britain in 1921, and performed invaluable work as assistant editor of the journal, first during 1928–30 and again from 1937 until his death. Many contributors have had reason to be grateful for the careful scrutiny which he gave their papers.

Wright's scientific work was noteworthy for its thoroughness and attention to detail, and his papers are models of lucidity. Perhaps his most important contribution was the convincing demonstration that the blood of a patient with subacute infective endocarditis was actively bactericidal, a conclusion made possible by his use of methods of quantitative cultivation. This necessitated research into the factors which tended to inhibit the growth of delicate pathogens in artificial media, and "Wright's" broth is well known as an excellent and easily prepared medium for the cultivation of such organisms. He always contended that one should work on problems which lay ready to hand for solution, so it was not surprising that when he came to Liverpool and found himself in charge of a large public health laboratory he should start investigations on the epidemiology of diphtheria, especially cross-infection in diphtheria wards, which had far-reaching practical results, and on the reliability of bacteriological analysis of water supplies. Many improvements in the technique for the isolation of intestinal pathogens also emanated from his laboratory, and he took the opportunity of a recent outbreak of paratyphoid *B* fever to write a masterly account of its bacteriology.

By his death, the University of Liverpool has lost a wise administrator and a stimulating teacher. He was one of the ablest of committee men, and no sub-committee of importance in the Medical Faculty was appointed which did not include him. At various times he acted as external examiner to the Universities of Leeds, London and Manchester.

Though ill-health attended Wright's later years it was borne with characteristic fortitude. He married in 1917 Matilda B. Spittal. Her death barely a month before his own was a grievous blow. Their three sons survive them.

A. C. T. VAUGHAN.

NEWS and VIEWS

Prof. J. K. Parnas

PHYSIOLOGISTS and others will be glad to learn from the following extracts from a card received by Prof. A. V. Hill that Prof. J. K. Parnas, till 1939 professor of medical chemistry in the University of Lwów, escaped to the U.S.S.R. and is alive and well:

"I am still in Ufa, in the Bashkiria, with my wife; my son is in Central Asia, in the Polish army. All my people, my pupils and friends, remained in Lwów, unfortunately, and I do not know anything certain about their fate. I myself had a narrow escape, the events have been so quick. I am living here quite comfortably and have good company of people from the Western Russian cities, and I am treated with so much consideration and given everything that can be given from the moment when they received me from Lwów. From time to time I am getting news of your activities through notices in NATURE and other periodicals. I hope the strange and tragical perturbations through which we are given to live will sometime ebb down, and I shall see my liberty, and my town again, and perhaps also my Western friends—and join them at some Physiological Congress. But verily I never shall forge these good and brave people here, and the time was living among them."

Population Statistics

The National Institute of Economic and Social Research is planning the issue of Occasional Papers to make quickly available the results of research which are of particular current interest. The first to be issued deals with "The New Population Statistics" and has been written by R. R. Kuczynski, a leading authority on the subject of population. The paper is a critical review of a memorandum presented by the Registrar-General to the Royal Commission on the Geographical Distribution of the Industrial Population more than three years ago but only recently made public. The author bases his criticism on a searching analysis of certain new fertility data collected under the Population (Statistics) Act of 1938, published this year in the Registrar-General's Statistical Review of England and Wales for 1938 (Tables, Part II, Civil), to which all students of population problems had been looking forward eagerly.

The study is divided into four short chapters. In the first two, Dr. Kuczynski discusses the new data and some of the results which may be deduced from them. In the last two he attacks the forecasts of the future population of Great Britain made by the Registrar-General and the remedies he proposes for them. The position, as the author sees it, is concisely stated in the final paragraph, which deserves quotation: "It would be most regrettable if the Registrar-General's conclusions should induce the general public to believe that the prevention of a population decline is an easy matter which can be achieved any time by very simple and immediately effective means. It is now more important than ever to realize that Britain's population problem is a serious problem and extremely difficult to solve. Fortunately, the new population statistics, if perused judicially, will somewhat facilitate that task."

Geology of the U.S.S.R.

According to the *Soviet War News*, reports from the Geological Committee of the Council of People's Commissars indicate that more than two thousand expeditions went out during the summer, and discovered valuable new deposits of strategic raw materials. A feature of war-time geology is that the exploitation of new deposits begins much earlier than it did in peace-time. New deposits of aluminium ores have been discovered in the Urals, in Western and Eastern Siberia, and also in Kazakhstan. The exploitation of newly discovered antimony and mercury deposits has already begun. Rich sources of iron ore, fluxes and fireproof minerals for the iron and steel industry have been opened up in the Urals, Siberia and the Central Asian Republics. Prospecting for combustible shales is meeting with success in the Urals and Eastern Siberia. Particularly important, from the point of view of defence, is the discovery of new sources of manganese. Several new manganese mines are already functioning in the Urals, Western Siberia and Kazakhstan. During seven months of 1942 the output of manganese ore in these regions was 250 per cent greater than in the parallel period of 1941.

Coal mines are being developed in the immediate vicinity of the Urals iron and steel industries. More than ten coal pits have been sunk in the recently discovered deposit in the middle of the Kizelovo district, and are already in production. An exhibition of the mineral wealth of Tadjikistan, the Soviet Republic north of Afghanistan, opened in Stalinabad, contains a collection of seventy specimens of useful minerals recently discovered in the Pamirs and in the mountains of Gissar and Zeravshan; among them are iron ore, tin, wolfram and lead.

The Leningrad Botanical Institute

The Leningrad Botanical Institute, the largest in the U.S.S.R., has not suspended its work under conditions of war and siege. The Institute has a rich botanical collection of some seven million specimens of plants. Its library contains 135,000 volumes on botany, while more than 20,000 specimens of plants from all parts of the world are to be found in its gardens laid out about 230 years ago on the order of Peter the Great. The hothouses alone of the Institute occupy an area of 35,000 square metres.

During the autumn of 1941, 193 scientific research workers and employees of the Institute remained in the city in order to preserve this valuable property, and not only did they preserve it under the very difficult conditions of the past winter but they also continued their scientific research work. While the Germans were shelling the city Prof. Rozhevits completed his monograph entitled "The Biology and the Economic Importance of the World's Cereal Plants".

Official Recommendation of Insecticides and Fungicides

With the concurrence of the Agricultural Improvement Council, a scheme under which official approval can be given to proprietary insecticides and fungicides for the control of plant pests and diseases has now been agreed by the Agricultural Departments of Great Britain and the Association of British Insecticide Manufacturers. The Minister of Agriculture and Fisheries and the Secretary of State for Scotland in consultation with the Agricultural Research Council, have appointed the following Committee to advise on applications from manufacturers for the approval of their products under this scheme: Prof. J. W. Munro (*chairman*), Dr. C. E. Foister, Mr. C. T. Gimingham, Mr. A. J. Holden, Dr. Hubert Martin, Mr. W. C. Moore, Dr. D. D. Pratt, Dr. H. Shaw, Dr. J. T. Martin (*secretary*). This Committee will be responsible for recommending approval. The principles and conditions of approval for the various groups of products will be drawn up by a joint panel composed of the members of the Committee, together with four representatives of the Association of British Insecticide Manufacturers, a representative of the Government Chemist and a representative of the Agricultural Research Council. This Joint Panel will also consider any points of principle arising out of particular products submitted for approval. Particulars of the scheme may be obtained from the Secretary of the Committee, Plant Pathological Laboratory, Ministry of Agriculture, Milton Road, Harpenden, Herts.

Study of the Atomic Nucleus

The University of Manchester branch of the Association of Scientific Workers has organized a series of lectures which are being given by scientific men engaged in research. The lectures are to cover various scientific topics, and it is hoped that they may help to establish contacts between scientific men working in widely different fields. Lectures have been given on "Relativity", "Heredity" and "Organic Chemistry". A meeting on October 14 was addressed by Dr. S. Tolansky on "The Study of the Atomic Nucleus by Spectroscopic Methods". After a short historical introduction, Dr. Tolansky discussed the spin of an atomic nucleus as one of the causes of the hyperfine structure of spectral lines. The importance of experimental technique in the study of hyperfine structure was stressed, attention being devoted to both sources and instruments. Typical hyperfine structures were illustrated and their interpretations discussed. It was pointed out that hyperfine structure investigations have yielded valuable information about nuclear moments, isotope abundance ratios, nuclear volumes and shapes of atomic nuclei. A theory of Landé was discussed according to which the spin and magnetic moments of atomic nuclei are determined by the spin and orbital motion of one neutron or proton only.

Indian Association for the Cultivation of Science

THE annual report of the Indian Association for the Cultivation of Science for the year 1941 includes the report of the committee of management and a list of papers published in the *Indian Journal of Science*, vols. 14 and 15, together with a report by Prof. K. S. Krishnan on the scientific work of the Association. This includes an account of magnetic studies on gadolinium sulphate octahydrate and of the spin-orbit coupling in cobaltous ions deduced from the magnetic properties of blue cobalt salts, in which results were obtained strongly supporting the theoretical prediction that there should be an inversion of the Stark pattern, first in a given cubic field as we pass from cobaltous to nickelous ions, and second for either of these ions as the disposition on the negative ions surrounding them changes from a tetrahedral distribution to an octahedral one. Reference is also made to magnetic measurements on a large number of cupric Tutton salts at low temperatures, in which also the cuprous ions possess practically the same type of anisotropy as in copper sulphate pentahydrate. The paramagnetic properties of several other salts of the iron group have been studied at low temperatures, and reference is made to the results obtained with some of the complex salts such as potassium ferricyanide. Preliminary measurements on the magnetic properties of mobile electrons in condensed ring hydrocarbons such as anthracene, chrysene, pyrene, etc., indicate that there is a decrease of the order of a few per cent of the diamagnetism of the mobile electrons as we pass from room temperature to about 300°. The metallic nature of the mobile electrons in aromatic molecules is supported by the observation that the absorption bands in the violet and in the near ultraviolet regions in anthracene crystals, presumably due to the mobile electrons, are paralleled by the strikingly selective refraction of the crystals in the region of these absorption bands, those wave-lengths that are strongly absorbed by the crystal being those that are strongly reflected from its surface. Measurements on the polarization of fluorescence of anthracene, phenanthrene, chrysene, and naphthacene in highly viscous solutions lead to the conclusion that the fluorescence is due either to a single linear oscillator or to a set of linear oscillators that radiate independently.

Institute of Tropical Medicine at Havana

THE August issue of the *Boletin de la Medicina Sanitaria Panamericana* contains an account of the Institute of Tropical Medicine of the University of Havana. It was created on December 8, 1937, under the direction of Dr. Pedro Kourí, who is professor of parasitology and tropical diseases at the University. Its function is threefold: teaching, research and treatment. The courses of instruction are attended by students and post-graduates, many of whom are foreigners. Most of the research is devoted to studies of hookworm, echinococcus, bothriocephalus, ascaris, strongyloides, fasciola, amœba and a new intestinal parasite first described in 1935, *Inermucapsifer cubensis* Kouri. The institute contains a Finlay Museum, which has a collection of anatomical specimens, parasites and other teaching material on permanent exhibition, laboratories, a department for drawing, photography, microphotography and microcinematography, and a free dispensary. In co-operation with other agencies, the institute carries on a campaign of popular education and prophylaxis against intestinal parasites. The official organ of the Institute is the *Revista de Medicina Tropical*.

Recent Earthquakes

A SLIGHT earthquake causing neither damage nor casualties took place at Almora in the United Provinces, India, on October 10, 1942.

A strong earthquake swarm has recently occurred in the Azores. All the islands have been affected, though the tremors were particularly violent in the Island of Fayal and in Sao Jorge. The shocks were continuing on October 17. Strong faulting has become apparent across the island of Fayal, and buildings have been affected. Further news is awaited from the islands and from seismological observatories.

Announcements

PROF. J. D. BERNAL, professor of physics at Birkbeck College, University of London, will deliver the first Sir William Bragg Memorial Lecture of the Chemical Society on November 19, at 2.30. The Lecture will be given at the Royal Institution, Albemarle Street, London, W.1.

PROF. P. A. BUXTON, director of the Department of Entomology of the London School of Hygiene and Tropical Medicine, will deliver the first Bacot Memorial Lecture of the Lister Institute of Preventive Medicine on October 30 at 3 p.m. The Lecture, which will be entitled "Bacot's Work on the Louse and some of its Recent Developments", will be given at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1, and is open to the public.

THE following appointments and promotions in the Colonial Service have recently been made: E. Bellis, agricultural officer, Kenya; S. H. Crowdy, agricultural superintendent, Gold Coast; A. C. Trueblood, agricultural officer, Nigeria; P. E. Weatherby, botanist, Uganda; B. C. Willis, agricultural officer, Northern Rhodesia; H. C. Dawkins, assistant conservator of forests, Uganda; B. Gilchrist, assistant conservator of forests, Tanganyika Territory; R. W. J. Keay, assistant conservator of forests, Nigeria; G. A. Steven, fisheries development officer, Sierra Leone; C. L. C. Bourne (assistant chemist), government analyst, British Guiana G. R. G. Kerr (senior assistant conservator of forests), conservator of forests, Nigeria; D. E. Faulkne (veterinary officer, Gold Coast), principal veterinary and agricultural officer, Swaziland; A. H. S. Vig (senior assistant agricultural officer), agricultura officer, Nigeria.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

On "Absolute Acceleration"

It is of interest to consider, in this the year of Newton's tercentenary, the present position of *acceleration* in Newtonian mechanics. The Newtonian equations of motion of a particle *in free space* are unaltered in form, as is well known, on transformation to any other frame in uniform relative motion, but this is not true for transformations to relatively accelerated frames. Hence the notion of "inertial frames"—frames for which the Newtonian dynamics holds good—frames for the existence of which, according to Einstein and Infeld in their book, "The Evolution of Physics", physics has been unable to account. The existence of inertial frames appears to indicate that any particle in the universe possesses an absolute acceleration.

But the universe is not 'empty space'. It is populated with galaxies, receding from one another and approximately (in the large) uniformly distributed. If we move our frame of reference from our own galaxy to the nucleus of an external galaxy, we should expect the Newtonian mechanics still to hold good—we cannot assume our own galaxy privileged. But according to Newtonian mechanics itself, a new term should appear in the equations of motion referred to the distant nucleus, a term arising from the acceleration of that nucleus relative to our own galaxy. Hence mechanics, in the distant galaxy, cannot be Newtonian, and we are driven back to assuming ourselves in a privileged position.

The explanation of this paradox can be deduced from two papers[1, 2] in 1934 on "Newtonian Expanding Universes", the first by myself, the second by Prof. W. H. McCrea and myself working in collaboration. We there showed that the relativistic equations of the expanding universe are identical in form with those derived on elementary Newtonian mechanics and gravitation combined with the hydrodynamical equation of continuity, provided that a nebular nucleus P is assumed to be under the gravitational attraction of all the matter inside a sphere centred at the observer O and of radius OP, O being supposed unaccelerated. The velocity-distance law of Hubble then followed. The deeper significance of this result was left over for further research. It is now clear that if the roles of O and P are interchanged, P should be able to assume himself as unaccelerated and O as having an acceleration determined by the matter inside the sphere of centre P, radius PO. In other words, the term in the equations of motion which would be expected on transforming from O to P is annihilated by the changed attraction of the matter of the universe.

This means that there is no such thing as absolute acceleration. By appropriate choice of observer O we can make P's acceleration what we will. Just as the Newtonian relativity of velocity can be stated in the form: "It is possible to assign the velocity of any one particle in the universe *arbitrarily*; the rest then follow", so we can assert a Newtonian relativity of acceleration in the form: "It is possible to assign the acceleration of any one galaxy *arbitrarily* (and with it the acceleration of any member of it); the rest then follow." Or we may put the statement in the form of one of Prof. E. T. Whittaker's Postulates of Impotence: "It is impossible to determine the absolute acceleration of any particle in the universe." The reconciliation of this state of affairs with the apparent conflict with the naïve view of Newtonian mechanics enunciated earlier is that we are not entitled to regard any particle whatever as 'in free space'; it is always exposed to the pull of the rest of the universe, which is reckoned differently by different observers. The occupation of the universe by matter attracting according to the inverse square law is an essential condition for the existence of inertial frames, and so for the world-wide validity of Newtonian mechanics. As in Einstein's theory, mechanics and gravitation are indissolubly connected in a proper representation of Newton's theory. We are indeed "encompassed by a great cloud of witnesses"—the hypothetical observers associated with the uncountable extra-galactic nebulæ that are their possible vantage-points.

Since the acceleration of any one nebula is assignable arbitrarily, the question arises whether we can go further and choose all the relative accelerations to be zero. It is clear that the extra-galactic nebulæ in a homogeneous expanding universe are 'equivalent' in the sense used by Dr. Whitrow and myself[3], and accordingly the observers associated with them can re-graduate their clocks and adopt a scale of time (t-scale) in which all the nebulæ are in uniform relative velocity. This leads to kinematic relativity, which, as I have shown in a recent series of papers[4], affords a purely deductive approach to mechanics and gravitation. The re-graduation of clocks transforms away the gravitational pulls between the fundamental particles of the universe, just as Einstein transformed away *local* gravitational fields; but it leaves persisting a gravitational field on a *general* free particle.

The non-existence of absolute acceleration has consequences which run right through physics. For example, on the classical theory of electromagnetism, an 'accelerated electron' was supposed to emit radiation, whereas an unaccelerated one did not. This result is now seen to be meaningless as it stands, for we are unable to assign a unique value to the acceleration f in Larmor's formula $\frac{2}{3}e^2f^2/c^3$. An electron on a distant nebula, if the latter is considered as accelerated relatively to us, would on the classical theory be considered as radiating; but when we take up our abode on the distant nebula itself, and regard it as now unaccelerated, does the electron cease to radiate? The explanation of this paradox is two-fold: in the first place, the scale of time in which the Maxwell theory of electromagnetism is valid is that in which the galaxies are relatively unaccelerated, namely, the t-scale, as is shown by the Lorentz invariance of Maxwell's equations; I developed the consequences of this in two papers in 1938. In the second place, the radiation calculated by Larmor's formula relates only to a small volume charge, and is invalid if an electron is a true singularity. There are other objections to the view that an accelerated electron necessarily radiates, but I am content here to point out that the non-existence of absolute acceleration requires substantial modifications in the classical Faraday-Maxwell theory.

Temperature Variation of Diffuse Scattering of X-Rays by Crystals

The theory of diffuse scattering of X-rays by single crystals subjected to thermal vibrations indicates that for temperatures near or above the Debye temperature, but not too high, the diffuse scattering power σ_B should be proportional to Te^{-T/T_0} where, for a cubic lattice, $T_0 = \frac{mk\,\Theta^2}{3h^2} \cdot \frac{a^2}{h_1^2+h_2^2+h_3^2}$ (T, absolute temperature; m, atomic mass in gm.; a, lattice constant in cm.; Θ, Debye temperature; k, h, Boltzmann and Planck constants; h_1, h_2, h_3, the Miller indices of the nearest Bragg reflexion).

TABLE 1.

Type of cubic lattice:	Face-centred			Body-centred		Pseudo-simple			Diamond
	Cu	Pb	Al	Li	Na	NaCl	KCl	KBr	C
Θ° K.	315	88	398	510	202	281	230	177	(1830→ 2340)*
$(h_1^2+h_2^2+h_3^2)\ T_0$° K	14450	6880	12260	3800	2970	12850	13670	14230	(89540→ 146400)

* The correct value to assume is doubtful, but is probably near 1900° K.

This expression assumes that the distribution of diffuse scattering power about the lattice point does not vary with temperature, which is true if the variation of the elastic constants with T is small. The function Te^{-T/T_0} has a maximum value for $T = T_0$, but the thermal theory as it stands does not necessarily hold up to this temperature, since when $T \rightarrow T_0$, an approximate expansion of the type $e^M = 1 + M$, which is used in the course of the derivation, becomes no longer permissible. It seems likely, however, that even a rigorous form of the theory would still give an inversion point, where the diffuse scattering, instead of increasing with temperature, would begin to decrease. Values of T_0 have been given by Sarginson[1] but these are in error by a factor of $4\pi^2$, and recalculation gives the values in Table 1.

			Mean observed %	135·5	151
			Calculated %	140	148

For high orders of reflexion the values of T_0 should, in some cases, be well within the limits of observation. Experiments are in progress to test this point.

Quantitative measurements of the temperature variation of the intensity of diffuse reflexion are not easy to make, but such measurements have already been provided by Laval[2] for the 002 and 004 scattering regions of potassium chloride at temperatures 290° K., 550° ± 10° K. and 665° ± 15° K. In Table 2 his data are given, first on an absolute scale, then with the high-temperature measurements expressed as a percentage of those at room temperatures; and finally his mean results are compared with those calculated from the expression

$$\sigma_B \propto T \,.\, e^{-T(h_1^2+h_2^2+h_3^2)/13670}.$$

The parameter ψ is a measure of the distance of the diffusely reflecting region studied, from the appropriate Bragg reflecting point.

The agreement is well within the limits of the (10 per cent) experimental accuracy claimed by Laval. Moreover, the comparative constancy of $\sigma_T/\sigma_{290° \text{K}}$. for different values of ψ (corresponding to a range of elastic wave-length 90 → 16·5 A. for 002, and 127 → 10·7 A. for 004) shows that it is legitimate to assume constancy of intensity distribution with change of temperature.

Laval himself did not realize how well his results confirmed the predictions of the thermal theory, and it is perhaps the more remarkable that he should have concluded his experimental study with the words "On peut espérer que la topographie des domaines de la diffusion forte apportera des renseignements précis sur la distribution de l'énergie entre les diverses ondes élastiques qui constituent l'agitation thermique."

Vitamin P in Blackcurrants

The necessity for finding sources of ascorbic acid other than citrus fruits has turned increased attention to the utilization of fruits produced in Great Britain and at the present time both wild and cultivated fruits are being studied in some detail. It is accordingly of interest to note that while blackcurrants, like the citrus fruits, provide a rich source of ascorbic acid, they have now been found to contain considerable quantities of the factor known as vitamin P which has hitherto been mainly derived from citrus fruits. The fraction showing vitamin P activity may most conveniently be isolated from blackcurrants by extracting the depectinized and concentrated juice with amyl alcohol. After the removal of the anthocyanins by extraction of the amyl alcohol solution with dilute hydrochloric acid, the material may be further purified by precipitating the active fraction from ethyl alcoholic solution as the lead salt by a method which is essentially that described by Szent Györgyi[1] for the preparation of 'citrin'. Decomposition of the lead salt gives a red-brown material which has not yet been obtained crystalline; it is soluble in water and appears to consist largely of glycosides of anthoxanthin type. The material has been isolated in a yield corresponding to 0·03 per cent of the original juice.

Biological tests have been carried out on this material by Mr. A. L. Bacharach in the Biochemical Department of Glaxo Laboratories, Ltd., by a method recently described[2], and it has been found that the material has an activity 100 times greater than that of recrystallized hesperidin and 10 times greater than hat of a water-soluble 'citrin' preparation derived from oranges. The blackcurrant product therefore provides a source of vitamin P in a relatively concentrated form suitable for further chemical study.

The hips of wild rose species, such as are now also being used extensively for the preparation of ascorbic acid concentrates, were shown as a result of biological tests by Zacho[3] to contain vitamin P. Preparations made from rose hips in this laboratory by methods imilar to that described above have been found to ontain a fraction resembling the blackcurrant material in its chemical behaviour.

Vitamin C in the Days of Francis Bacon

In recent years the history of the deficiency diseases, caused by lack of the substances which we now call vitamins, has been carried back further into the past by various discoveries in the older literature of science and medicine[1]. In the published results of these historical inquiries I have not seen any allusion to the following remarkable passage in the "New Atlantis" of Francis Bacon which was written about 624.

> "We sailed from Peru . . . by the South Sea, taking with us victuals for twelve months and had good winds from the east, though soft and weak, for five months' space and more. . . ." When they at last sighted New Atlantis ". . . our sick, they were many, and in very ill case, so that if they were not permitted to land, they ran in danger of their lives . . . we were in all, sick and whole, one and fifty persons, whereof our sick were seventeen." One of the inhabitants of the island came aboard "holding in his hand a fruit of that country, like an orange, but of colour between orange-tawny and scarlet, which casts a most excellent odour: he used it, as it seemeth, for a preservative against infection." After the authorities had given permission to land "there were brought in to us great store of those scarlet oranges for our sick, which, they said, were an assured remedy for sickness taken at sea." During the next three days "we had every hour joy of the amendment of our sick, who thought themselves cast into some divine pool of healing, they mended so kindly and so fast."

The "New Atlantis" is, of course, fiction, a short 'novel with a purpose' in fact, and cannot be adduced as direct evidence of the scientific knowledge of the time. But this narrative of a large part of a ship's crew incapacitated by illness after a voyage of five months, and the rapid recovery of the sick men when fresh fruit was obtained, corresponds so closely to the picture of an outbreak of scurvy, counteracted at once by a supply of vitamin C, that it is very unlikely to have been an invention. Harris[2] says, ". . . in the ships of the East India Company, oranges or lemons or lemon juice had been used regularly as antiscorbutics from 1601 onward: they had been introduced into the Company at the instigation of Sir James Lancaster, who had demonstrated their value on his 'privateering expeditions'." This practice is probably the source of Bacon's information, and his allusion to this subject in the "New Atlantis" illustrates the width of his knowledge.

Mechanism of Sensitivity Changes of Sense Organs

It is at present an established fact that the dark-adapted eye alters its sensitivity when acoustic stimuli are applied to the ear (Lazarev, Kravkov and others) or when olfactory stimuli act upon the olfactory organ (Makarov), etc. We have succeeded in showing that similar changes, either towards increase or decrease of eye sensitivity, are caused by taste stimuli (sweet, acid, salt or bitter) as well as by temperature (cold or heat) and tactile stimuli.

However, the eye is influenced not only by stimulation of extero-receptors (external organs of sense). Regular shifts of thresholds of peripheral vision have been produced by changing the volume of the stomach or of the urinary bladder by means of tepid water or physiological saline. Finally, a similar effect was elicited by the extension of articular capsules of muscle tendons and of muscles themselves. Thus stimulation of extero-, intero- and proprioceptors always results in change of sensitivity of dark-adapted eye. In other words, sufficiently strong stimulus applied to any area of receptive field of the human organism immediately affects functional properties of the eye. There is experimental evidence to show that the eye is no exception in this respect, and that all organs of sense of man undergo some changes in sensitivity upon excitation of any other organ of sense (interaction of afferent systems).

It was suggested several years ago by L. A. Orbeli from his own morphological and physiological evidence that an increase or decrease of sensitivity of receptors is due to the vegetative nervous system. This hypothesis has been checked by means of the above method.

First of all, parallel records were made in one of a series of experiments on thresholds of the dark-adapted eye, of frequency of pulse, and of electrical resistance of skin to constant current during and after excitation of various organs of sense (taste and temperature receptors). It was found that decrease of thresholds of peripheral vision is almost always accompanied by acceleration of pulse and change in skin resistance. The last-mentioned two functions are well known to be controlled by the vegetative nervous system.

In another series of experiments, the olfactory receptor of subjects was stimulated by sympathomimetic (geraniol) and parasympathomimetic (thymol) olfactory agents. In the first case sensitivity of eye as well as pulse frequency underwent increase, while in the second case the effect was opposite in character.

Finally, in a third series of experiments, use was made of the so-called vegetative tests (Anshner-Danini, Abrams, Luga, and others). It is a well-known fact that pressure exerted on the eyeball, palatum durum or the vertebra invariably causes change in pulse frequency. According to our expectations, change was also noted in the sensitivity of a dark-adapted eye, the two series of changes showing parallel courses.

Thus it will be concluded that change in sensitivity of the eye is effected by the vegetative nervous system in accordance with Orbeli's hypothesis. Change in functional properties of one organ of sense caused by stimulation of another sense organ is therefore to be regarded as a senso-sensory vegetative reflex, which in its turn is part of a diffuse reflex of the vegetative nervous system involving also the heart (senso-cardial reflex) and skin (senso-cutaneous reflex), as well as other organs and systems of the human body. Glucose-Excretion by the Rabbit Kidney

WORK carried out in this laboratory has proved[1] that the glucose threshold in the rabbit kidney is stabilized in the neighbourhood of a plasma concentration (C_b) of 240 mgm. per 100 mil. plasma (mgm. per cent) when the animal is under the influence of urethane. In a few rabbits the threshold level under urethane was higher than 300 mgm. per cent, but the bulk of the observations fell between 200 and 260, with a marked modal peak at 240 mgm. per cent. Large doses of insulin—approximately 10 units/kgm.—had a doubtful effect on the urethane threshold level, depressing the mean threshold from 282 to 243, which is not a significant change. More recent work[2] has shown that under nembutal narcosis, insulin, 1 unit/kgm., develops a marked depressant effect on the threshold level, and may indeed cause a rise in urine glucose, measured as fermentable reducing substance, at a time when C_b is falling.

It will be noted that the dose of insulin necessary to lower the threshold in the rabbit under nembutal narcosis is approximately one tenth the dose which in the urethanized rabbit produced a minimal effect. This indicates that urethane inhibits some of the effects of insulin, and the implications of this discovery are discussed in a recent publication[2].

Adrenalin causes a marked rise of threshold in the rabbit both under urethane and nembutal narcosis[2]. The threshold in the unanæsthetized rabbit is in the neighbourhood of $C_b = 120$ mgm. per cent. Unpublished results on normal young men show that the insulin effect may be elicited sometimes. The adrenalin effect has been shown to occur in renal glycosuria.

The investigation is continuing.

Records of Lancashire Cetacea

As records of Lancashire cetaceans are few, I thought it worth recording that when told of a 'big porpoise' washed up on the west Lancashire coast at Birkdale, Southport, on September 23, 1942, I identified it as a young male bottle-nosed dolphin (*Tursiops truncatus* Montagu) and took the following measurements: length 105 in., flippers 14 in., tail flukes 21 in. across, girth of body 50 in., depth of body 22 in., 'bottle nose' extension of upper jaw 5 in., 22 pairs of teeth in upper jaw, and probably same in lower but a few were removed by souvenir-hunters. Upper parts black, also flippers; underparts pale grey. The only previous Lancashire record I can trace was a specimen stranded at Walney Island on August 8, 1917[1].

On December 10, 1939, when a reported 'killer whale' was stranded alive by the flood tide on the Mersey bridge pontoons at Widnes, I was surprised to find that no one had gone to investigate it, and when I got there it had been cut up and returned to the river, but I obtained sufficient press photographs to identify it as Risso's grampus (*Grampus griseus* and sent a photographic print to the Liverpool Museum, which was later sent to the British Museum I also obtained a film strip of Leica negative of various positions of the specimen and sent this in to Liverpool Museum to authenticate the record, but unfortunately a year later, when the Museum was burned in an air raid, these negatives had not been developed and they were lost in the fire. Measurements and details I secured at the time from those who killed the specimen at Widnes, and from the photographs were: length 11½ ft., no teeth in upper jaw, a few teeth in lower jaw ¾ in. apart and blunt; body marbled and streaked with greyish-white, underpart smooth; long, narrow, white flippers; tail fluke long and narrow; dorsal fin tall; white about the muzzle; lower jaw shorter than upper jaw. Total weight about two hundredweights. It was alive an 'blowing' when caught by the men. A recognizabl photograph appeared in the *Liverpool Post* and othe local papers. There is no previous Lancashire record but in the north-west area one was recorded at Bardsey in 1933 and there is a much older Solwa record. ERIC HARDY.

FRESHWATER FISHES

THE work of the Freshwater Biological Association of the British Empire shows a large amount of activity on the part of all workers*. Naturally research on fishes takes the lead and much that is of real economic importance has been achieved. Of outstanding interest is the successful commercial perch fishery on Lake Windermere. This is an excellent example of a practical application in war-time of research carried out previously with purely scientific motives (see NATURE, 148, 651; 1941). Work on the study of the perch in Windermere was begun in 1933–35 by Mr. K. R. Allen who demonstrated by the use of traps that perch migrate into the shallows in spring. This resulted later in large-scale use of traps in catching perch by the ton with little labour and on a commercial scale. A firm of canners has now marketed the canned fish as 'Perchines' which have had a very favourable reception, and from the financial point of view also the project was a success. Traps were tried on other lakes which gave good results and the Ministry of Agriculture and Fisheries has decided to organize fisheries similar to that on Windermere on six lakes, two more being arranged by private enterprise. It is possible that in some of the lakes other fish, such as eels and pike, which enter the traps in pursuit of the perch, may be an even more valuable catch. The possibility of expanding the industry to water outside the Lake District is now being explored. It is expected that the rod fisheries will be improved by the reduction in number of perch, pike and eels. In Windermere the examination of changes in the flora and fauna due to the reduction in perch is being undertaken.

Since the beginning of the War the Association, in co-operation with the Ministry of Agriculture and Fisheries, has devoted much attention to the fact hat British waters could, and should, produce all he eels imported from the Continent during times of peace, and many more besides. Experiments were begun in 1941 in connexion with eel-fishery, on the use of artificial light for deflecting silver eels into traps. Although so far they are not conclusive it was confirmed that silver eels react to light more or ess in the way expected, and that there are no erious practical difficulties, even in war-time, in the way of rigging lights to be seen under water by migrating eels. With one of these systems of lighting bout half the eels from both natural and artificial runs swimming down one side of the stream were deflected to the other side. It was also found during hese experiments, by the use of traps divided horizontally, that about one third of the eels were swimming nearer the surface than the bottom. As is generally assumed that the migrating fish swim lose to or along the bottom of rivers, this fact may e important when reconsidering the design of ommercial traps.

Miss Winifred Frost has been working on various shes and has advanced steadily our knowledge of he freshwater life of British eels. Drainage basin vers ascending the rivers in spring, yellow eels habiting the lakes, and silver eels descending to he sea in autumn have all been examined. Otoliths nd scales were used, although these are not truly tisfactory for age growth determination in eels bove 40 cm. in length. The results show that all the silver eels and the great majority of yellow eels examined were female: presumably nearly all males live in or near the estuaries. About eight years of freshwater life takes place before the eels attain a length of 40 mm. and a weight of ¼ lb. After that the growth varies widely until the fishes migrate to the sea as silver eels after 10–17 years of freshwater life. The silver eels range in length from 47 cm. to 94 cm. and in weight from 7 oz. to 4 lb. Many of the eels examined for food contained molluscs, fishes and insects. Molluscs were common in the yellow eels, which also contained minnows, perch and caddis larvæ. Some of the silver eels contained perch, minnows and caddis flies. Elvers taken from the River Leven just after their entrance into freshwater were feeding heavily on chironomid larvæ—a common food of the trout.

Miss Frost's work on minnows shows that they are important competitors for food with young perch and trout, while although the char and the young perch are both plankton feeders they usually eat different species.

Artificial fertilization of char eggs and rearing of fry are being carried out at Wragmere fish hatchery. The fry are reared more easily than the trout until the complete absorption of the yolk, but after that they present difficulties in the fry ponds. It is hoped to rear the fry in boxes in the lake where natural plankton food will be available. Growth-rate and feeding habits in the trout from different localities are being studied and successful cross fertilizations have been made between brown trout, Windermere char and the American brook trout or char.

RADIO RESEARCH

IN his inaugural address as chairman of the Wireless Section of the Institution of Electrical Engineers, delivered on October 7, Dr. R. L. Smith-Rose dealt first with the history and growth of the Wireless Section, then with the work of the Radio Research Board; and finally he presented a survey of the present state of our knowledge of the speed of travel of electric waves of all wave-lengths from the visual to the radio-frequency spectrum (the substance of this last section appears on p. 477).

The Wireless Section of the Institution is just over twenty-three years old, in which time its membership has grown to more than eleven hundred. The Section has held 163 formal meetings, at which addresses and papers have been delivered, while informal meetings have been arranged from time to time to discuss topical technical subjects. In 1926 a report presented to the Council of the Institution by the committee of the Wireless Section referred to a proposal which was then being mooted in some quarters to form a new Institute of Wireless Engineers. The report suggested that such a step was unnecessary and would not be supported by representative and qualified wireless engineers. It was explained that an engineer with adequate wireless qualifications could become a corporate member of the Institution, and that other wireless engineers not reaching that standard were eligible as graduates, and as such could attend all meetings of the Wireless Section as well as of the Institution. Furthermore, the committee recommended that while it was essential that the standard of qualifications for membership of the Institution should be maintained, more opportunity should be afforded to the physicist engaged in wireless work to become a member of the Institution. This recommendation was approved by the Council and has continuously been acted upon by the committees responsible for electing new members; it is particularly opportune to direct attention to it at the present time, when a large number of men engaged on wireless work would probably refer to themselves as radio physicists rather than wireless or radio engineers.

Among other recommendations made in the report referred to above was one to the effect that all papers and discussions of a wireless nature should be published in a separate *Proceedings of the Wireless Section* as well as in the *Journal* of the Institution. For this every member of the Wireless Section must be very grateful. Fifteen volumes of these *Proceedings* were published during the period 1926–40, and these contain a most valuable record of the progress of wireless engineering research and development in a very compact form and free from the large mass of other papers published by the Institution and in which the wireless engineer has little more than general or passing interest. With the revision of the form of the *Journal*, which was necessitated by paper shortage considerations in 1940, the existence of these *Proceedings* formed a most valuable precedent for ensuring that papers on wireless were still published separately as Part III of the present-day *Journal*. It is very clear that as regards the provision of scope and opportunities for publication, no separate society or association could serve its members better than the Institution has done during the past sixteen years and still continues to do in a very satisfactory manner.

Dr. Smith-Rose next referred to the work of the Radio Research Board, with which he has been associated since its establishment in 1920 under the Department of Scientific and Industrial Research. Although concerned mainly with investigations of a fundamental nature, many of the aspects of the Board's programme are determined from time to time by the needs of the defence departments and of the Post Office and B.B.C., each of which has been represented on the Board itself and on all its technical committees. The Board makes its recommendations to the Department of Scientific and Industrial Research, which is responsible for providing the means and facilities for the conduct of the work; in recent years practically the whole programme has been entrusted to the Radio Department of the National Physical Laboratory for execution. Apart from the official reports of the Radio Research Board issued from time to time, the majority of the investigation work has been described in papers and reports published by the Institution of Electrical Engineers and other scientific societies. As an indication of the widespread nature of this publication it may be pointed out that of the 246 papers that have been published in the *Proceedings of the Wireless Section* during the past sixteen years, no less than eighty of them have been presented by staff working under the auspices of the Radio Research Board.

Little can be said about the recent investigations in hand, since for the past three years the work has been devoted entirely to the furtherance of the prosecution of the radio technical war in the manner in which is considered to be most useful. A conspicuous feature of this recent work has been to realize the fruition in direct Service application of all the long-term investigations sponsored for many years past by the Radio Research Board. The present value of pre-war fundamental work on direction-finding and ultra-short-wave propagation, suitably oriented to meet present conditions, is immediately obvious; but by now most of the apparently more academic subjects under investigation have suddenly been elevated to Service applications of the highest priority. Even some of the research items which had been abandoned in the past as having little or no interest have had to be revived to meet pressing demands, and it is often the fact of having already explored the technique and satisfactorily established the fundamental principles of a particular field that provides the advantage over the enemy in the technical conduct of the war. In some spheres the demand is for basic principles of design of apparatus and equipment which was developed originally as a research tool, and now has to be adapted to more practical application; in other spheres it is accurate measuring equipment and technique that is sought; while in yet other directions the request is for information that will define the present possibilities of radio communication, and more especially what these are likely to be in the immediate future.

AUSTRALIAN ASSOCIATION OF SCIENTIFIC WORKERS

THE Australian Association of Scientific Worker called two conferences of scientific workers—one in Sydney on February 21–22, and one in Melbourne on March 7–8—to consider the use being made of scientific men in Australia in furthering the wa effort.

The Melbourne Conference was attended by about one hundred and thirty members. Industrial undertakings and Government enterprises were almos equally represented; the younger members were in great majority. There was apparent a certain restraint in expressing views, possibly due in part, a least, to the more senior members not giving a lead There was no doubt at all of the sincere wish to giv all services required, but there was apparent dee misgivings whether the Government understood an appreciated what could be done—and can be done—by scientifically trained people given problems t solve; indeed, the opinion was expressed that the scientific men themselves had a duty (1) in seeing fo themselves what problems needing immediate solution already existed, (2) in anticipating problems tha would inevitably arise, and (3) in suggesting method of solution and carrying them out. But the doub was raised whether the Government has confidenc in scientific men, or whether it is just a lack of understanding on the part of the scientific men of politic methods.

Among the more important problems discusse were: lack of understanding of industrial fatigue absence of suitable bodies to study this problem factories; the inability to make use of experienc gained elsewhere; lack of foresight in planning fo supplies, especially in agriculture, and in poolin information of plant practices; the wastage scientifically trained man-power in the Fightin Forces.

It was stated that little or no use is being mad of the professional registers; and that the examin tion of inventions is neglected in many cases. Waste and by-products useful in certain industries are being neglected, while other industries could put many of them to good use, and have, in fact, been wanting some of these products. There appeared to be lack of co-ordination of efforts in industries engaged on similar work.

In short, problems which have been engaging the attention of scientific men in Great Britain, and many of which have been solved, are being experienced in Australia also.

The results of the debates were crystallized in ten resolutions which are now being communicated to the appropriate authorities. It is hoped that action will be taken by the Government. The Australian Association of Scientific Workers proposes to watch developments, and will make use of its special knowledge to see that better use is made of Australian scientific resources and man-power.

PACIFIC RELATIONS IN THE POST-WAR WORLD

THE second of the series of reports on the United States in a new world, based on the findings of a committee of the editors of *Time*, *Life* and *Fortune* set up to study post-war problems, is of particular interest as indicating the trend of advanced American thought on Pacific relations. The proposals are based on a belief in the greatness of Asia, and on the view that progress towards free and more abundant life in times of peace must be mainly concerned with a practical solution of the problems of productivity, literacy and common law and order, and that the East needs the social inventions of the West just as much as its technology. It is assumed that in the largest degree the peoples of Asia must work out their own solution, and the preference for strong and effective international authority is clearly indicated; although it is recognized that the United States may, in certain circumstances, have to be the principal trustee of the United Nations, while others are growing into modernity or recovering from the consequences of the War. The report proposes an organization to be called the Pacific Council, which would be the final judicial authority of the United Nations on Pacific affairs, although for the co-operative international administration required in specific jobs, the organization of special co-operative bodies is suggested, representing only those members of the United Nations which have a legitimate interest in the specific tasks.

The first of these tasks proposed is that of creating a nation in South-Eastern Asia. Coupled with an independent Philippines, it is suggested that new States should be created out of the other ex-colonies of Indonesia. The first and largest of these States would consist of Thailand, British Malaya, all the British and Dutch Islands in Indonesia and Portuguese Timor, with the political status of an international republic, in which it is suggested the ability and responsibility of the Dutch Colonial administrators will find ample scope. For the creation of this State the ultimate reasons are military and economic. In regard to Burma, it is suggested that Great Britain should transfer its rights to an international commission, on which Great Britain, India, China and the United States would be strongly represented, which would conclude an agreement with China concerning its transit rights on the Burmese roads, railways and rivers, and in the port of Rangoon. The first task of this commission would be that of physical reconstruction. It is suggested that France might be induced to agree to a similar course for Indo-China, after the preliminary restoration of French sovereignty.

While long-term control and disarmament of Japan is not considered feasible, it is suggested that if an American-Chinese-British-Dutch Group took over the Japanese aviation monopoly and its installations under a contract to run for 25–50 years, its operation would preclude any effective secret Japanese rearmament. Transfer of Japanese investments in Manchuria and China to China is suggested, and control of Japan's merchant marine should be vested in a Combined Shipping Board. The best hope for a change of heart in Japan is regarded as lying in the total discrediting of its military leaders and their followers, and in a resulting resolve of the Japanese people themselves to oust them.

With regard to China, the more serious specific problems to be solved are those of agriculture, industrialization, the restoration of an economic industrial balance, transport and education. All these principal problems are interrelated and formidable, but the building of a strong and free China is a Chinese task. The interdependence of China and other nations including the United States is recognized, however, and industrialization can only come naturally as part of a general international expansion if China is certain that such international economic expansion will occur, as expansion depends fundamentally on American participation. The approach to post-war economic relations can only be freed from mutual suspicion by a better understanding of the facts. The Chinese problem is to secure the essential financial and technical assistance from abroad, without paying for it through impaired sovereignty or the loss of control over national resources. The report strongly supports the participation in a free market area open to every nation, and Chinese exports should not be debarred from American markets by high duties. Economic relations with China require the admission of Chinese goods in payment of Chinese obligations, and the cheap imports would benefit the general United States public.

The danger to American industry and standards of living is discounted, and it is considered that one article of the mutual aid agreement should keep Asiatic, and especially Chinese, protectionism within bounds. These are the general principles for future and long-range application, and immediate measures should be taken with these objects in view. Reconstruction grants on a minor scale should greatly assist co-operation in the field of higher education, and the services of highly skilled scientific men and technicians are likely to be in very high demand in post-war China. The report frankly faces the changes in the American immigration law, which, like changes in the tariff, will be required. Leading problems of Korea, India, the South Pacific and New Zealand are briefly reviewed, and while the idea of a Pacific counterpart of the Atlantic Charter is discounted, the importance of establishing cordial confidence as a basis of unity and high morale in the United Nations is emphasized.

OTOLOGY AND FOLKLORE

IN a recent paper (*J. Laryng. and Otol.*, 57, 311; 1942) on this subject, Dr. J. D. Rolleston stated that though Toynbee is generally acknowledged to be the founder of modern otology, the first recognition of ear disease can be traced back to the Ebers papyrus, which contains a monograph on "ears hard of hearing" and on "ears from which there was a putrid discharge". Although there is an enormous amount of literature connected with the history of otology, the only comprehensive study of the folklore of this speciality is that furnished by Hovorka and Kronfeld in their treatise on comparative folk-medicine.

Among the numerous popular beliefs and superstitions connected with the ear, the most interesting to folklorists and students of the history of religions is the idea of the ear serving as the female organ of generation, particularly in the conception of Jesus, which was supposed to be effected by introduction into the Virgin Mary's ear of the breath of the Holy Ghost. Belief in this unusual function of the ear, which was often illustrated by medieval artists, is not peculiar to Christian mythology; it is also found in Mongolian, Persian and Indian legends. A belief in a relation between the size or shape of the external ear and the character of the individual was widespread, small ears being a sign of mental power, large ears indicating dullness, and pointed ears a bad character.

The belief that tingling of the ear is a sign that others are speaking of you dates back to the time of Pliny, who stated that this was then a universally accepted notion.

A belief once prevalent in the north-east of Scotland was that deaf mutes possessed the faculty of looking into the future and discovering what was hidden to others.

In accordance with the rule that prophylaxis is much rarer in folklore medicine than curative measures, there are comparatively few instances of preventive measures employed against ear disease, and, such as they are, consist mainly of amulets. Therapeutic treatment, on the other hand, was abundant, and can be classified under the headings of animal remedies, including coprotherapy, plant remedies, mineral remedies, hydrotherapy, invocation of patron saints and miscellaneous remedies.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk are open to the public*)

Monday, October 26

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE (at 28 Portland Place, London, W.1), at 3 p.m.—Prof. J. C. Drummond: "The Background to the Study of Nutrition in War-Time" (Harben Lectures, 1).*

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8 p.m.—Miss Mildred Cable: "A New Era in the Gobi".

Tuesday, October 27

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE (at 28 Portland Place, London, W.1), at 3 p.m.—Prof. J. C. Drummond: "Deficiency Conditions to be guarded against in War-Time" (Harben Lectures, 2).*

Wednesday, October 28

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE (at 28 Portland Place, London, W.1), at 3 p.m.—Prof. J. C. Drummond: "Measures taken to Maintain a Good Nutritional Condition of the People in War-Time" (Harben Lectures, 3).*

Thursday, October 29

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 2.15 p.m.—Mr. T. Besterman: "A Projected Bibliography of Dictionaries"; Mr. S. J. Astbury: "The Bibliography of Petroleum".

Friday, October 30

LISTER INSTITUTE OF PREVENTIVE MEDICINE (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 3 p.m.—Prof. P. A. Buxton: "Bacot's Work on the Louse and some of its Recent Developments" (First Bacot Memorial Lecture).*

FREE GERMAN INSTITUTE OF SCIENCE AND LEARNING (at 16 Buckland Crescent, Hampstead, London, N.W.3), at 8 p.m.—Dr. K. Mendelssohn: "Temperatures near Absolute Zero".*

Saturday, October 31

INSTITUTE OF PHYSICS (ELECTRONICS GROUP AND MIDLAND BRANCH) (at the College of Technology, Rugby), at 2.45 p.m.—Dr. D. Gabor: "Electron Optics".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT MASTER TO TAKE MATHEMATICS, ENGINEERING DRAWING, AND ENGINEERING SCIENCE—The Principal, Enfield Technical College, Queensway, Enfield, Middlesex (October 30).

LECTURER IN ENGINEERING—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (October 31).

GRADUATE OR NON-GRADUATE TEACHER OF ENGINEERING SUBJECTS, INCLUDING WORKSHOP INSTRUCTION, at the Grimsby Technical College—The Director of Education, Education Offices, Eleanor Street, Grimsby (October 31).

LECTURER IN MECHANICAL OR ELECTRICAL ENGINEERING—The Registrar, Loughborough College, Loughborough, Leics. (October 31).

LECTURER IN CHEMISTRY at the Technical College, Cardiff—The Director of Education, City Hall, Cardiff (November 1).

TEACHER IN THE ENGINEERING DEPARTMENT—The Principal, Municipal Technical College, Halifax (November 2).

TEACHER TO GIVE INSTRUCTION IN THE ENGINEERING WORKSHOPS—The Principal, Municipal Technical College, Halifax (November 2).

CHIEF ASSISTANT ENGINEER—The General Manager, Port of Bristol Authority, Docks Office, Queen Square, Bristol 1 (endorsed 'Chief Assistant Engineer') (November 7).

TWO INSTRUCTORS FOR DAY CLASSES FOR TRAINING OF MARINE ENGINEERS, at the Stow College, School of Engineering—The Director of Education, 129 Bath Street, Glasgow, C.2 (November 20).

LECTURER FOR THE ENGINEERING DEPARTMENT of the Stockport College for Further Education—The Director of Education, Education Offices, Town Hall, Stockport.

LECTURESHIP IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Principal, Central Technical College, Suffolk Street, Birmingham 1.

A CENTRAL PLANNING AUTHORITY

WHEN the Uthwatt Committee issued its interim report in July of last year, Lord Reith announced that all necessary preliminary steps towards the working out of a national plan of reconstruction and development should be taken as soon as possible. The Committee itself based its interim recommendations on the assumptions that a central planning authority would be established without delay and would proceed with the working out of a national plan. The final report of the Committee, published a few weeks ago, shows clearly that it proceeded with its work in this conviction, reached at an early stage in the inquiry, that a central planning authority with a positive policy for such matters as town and country planning, agriculture, industrial development and transport is essential to an effective physical reconstruction of Great Britain after the War. That case is put with admirable firmness and lucidity in the final report. Yet, as Lord Reith pointed out in initiating a debate on the subject in the House of Lords on October 22, the Government has contented itself with a statement of general approval only. Something more is needed at once. Lord Reith pressed for the immediate creation of machinery for national planning under a Minister of National Development. This proposal is an advance on the position taken up by Lord Reith early this year while he held office as Minister of Planning, and he explained that his earlier statement represented all he could obtain at the time.

The final report of the Uthwatt Committee takes its place with those of the Scott Committee (see NATURE of October 17, p. 441) and of the Barlow Commission in completing the survey of the steps to be taken to prevent the work of reconstruction in Great Britain from being prejudiced by haphazard development or by the misuse of land. In many respects the Uthwatt Report is more technical and specialized than the other two, and goes very thoroughly into details which the layman may find it difficult to grasp. None the less, the general principles and recommendations are presented with remarkable lucidity, and its cogent arguments should be followed by all without difficulty.

The report opens with a quotation from the first report of the Scott Committee appointed towards the close of the 1914–18 War, which illustrates the measure of the failure of the past twenty years to adapt planning policy and methods to the needs of the situation. It raises for examination the general question whether the measures of legislation designed in recent years to secure a better utilization of land resources and to lead to an amelioration of the living conditions of the people, of which the Town Planning Acts and the Housing Acts are perhaps the most important, are based on a foundation adequate to ensure their successful operation. It constitutes a warning which cannot be ignored that the many problems involved may not be capable of solution by a system of patchwork amendments of the existing code of law or piecemeal adaptation of the existing procedure, and that a fundamentally new approach to the whole problem may be inevitable to find a satisfactory basis for any adequate measures of reconstruction and post-war planning.

The Uthwatt Committee is clearly concerned, as Mr. George Hicks told the House of Commons last year, with problems which go to the root of our economic life. Historically, its terms of reference arise out of the evidence placed before the Barlow Commission, that "the difficulties that are encountered by planning authorities under the existing system of compensation and betterment are so great as seriously to hamper the progress of planning throughout the country". These difficulties, already acute in peace-time, are now thrown into sharper relief by the effects of the War, and the leisurely trend of opinion in favour of a securer basis for planning has become an urge for action. The emphasis on reconstruction, not only as an immediate necessity for repairing the devastation caused by the War, but also as a long-term measure, has led the Committee to consider in broad outline, as its first duty, the general requirements of post-war reconstruction and the scope and object of planning.

In regard to the first, replacement of buildings destroyed during the War is popularly regarded as the main objective; but where large areas have been laid waste, they may well need to be replanned in the light of modern requirements, and this cannot be done in isolation. It must form part of a long-term policy for the town or city concerned, and for adjoining areas. Moreover, there are innumerable areas in many towns and cities which urgently need modernizing to meet present-day requirements, and the complete reconstruction of such areas is as important as the rebuilding of war-devastated areas; the two tasks should be regarded as different parts of a single problem.

This, however, is only a small part of the picture. The requirements of agriculture, the location and re-establishment of industry for peace-time production, the elimination of congestion from built-up areas, the building of adequate housing accommodation, the provision of open spaces, green belts and other amenities, the development and concentration of public utility services, the overhaul of our transport and communication system, the requirements of post-war development in civil aviation, and the relation of all these matters to the demands of future defence—all these are problems which must be considered when plans for the post-war period are being formulated. It is essential to use the relatively small area available to achieve properly balanced and co-ordinated planning of the whole, as contrasted with the confused development in the past in an isolated and regional manner. The Committee's recommendations are framed, therefore, to provide a basis for whatever policy may be adopted, so that it may be freed from any elements which might hamper, prejudice or delay its effective execution.

In regard to the evolution of planning, the Committee observes that the most important general defects of the present system, under the 1932 Town and Country Planning Act, are that the planning powers are permissive only; the planning schemes are necessarily local, not national, in outlook; and the planning powers of local authorities are largely regulatory in character and do not, except to a limited degree, enable them to undertake or secure positive development. Moreover, while this planning system, handicapped by these defects and by the absence of central positive direction, is inadequate to secure the best social use of the land of Great Britain, it is also clear that the evolution of planning principles and practice has not kept pace with the economic, industrial or strategical requirements of the country. That much was clearly established by the Barlow Commission, the recommendations of which mark a turning point in the evolution of planning in Great Britain and lead naturally to the assumptions upon the positive aspects of planning on which the Uthwatt Committee bases its recommendations.

The first assumption is that national planning is intended to be a reality and a permanent feature of the administration of the internal affairs of Great Britain. It is assumed that planning will be directed towards ensuring that the best use is made of land in order to secure economic efficiency for the community and well-being for the individual, and that it will be recognized that this involves the subordination to the public good of the personal interests and wishes of landowners. Unreserved acceptance of this conception of planning is vital to a successful reconstruction policy, for every aspect of a nation's activity is ultimately dependent on land. The difficulties in regard to compensation and betterment arise fundamentally from the existing legal position with regard to the use of land, which attempts largely to preserve, in a highly developed economy, the purely individualistic approach to land ownership.

Recognizing that town and country planning is not an end in itself, but the instrument for securing that the best use is made of the available land in the interests of the community as a whole, and as such must advance with the condition of the society it is designed to serve, the Committee assumes, secondly, that the system required for effective reconstruction is one of national planning. This requires a high degree of initiative and control by the central planning authority, which will have national as well as local considerations in mind, will base its action on organized research into the social and economic aspects of the use and development of land, and will have the backing of national financial resources where necessary for a proper execution of its policy.

These assumptions should be kept in mind if we are to appreciate the spirit and logic of the report. They are implicit in the lucid analysis of the nature to existing difficulties which follows, where, in regard of undeveloped land, stress is once more laid on the importance of organized research into national requirements. Clearly, under a system of well-conceived planning, the resolution of competing claims and the allocation of land for the various requirements must proceed on the basis of selecting the most suitable land for the particular purpose, irrespective of the existing values which may be attached to individual parcels of land. To forbid building in a coastal area or a beauty spot, or because the soil is highly fertile, or to prevent some of our existing large cities from expanding further will involve sterilization from building of such land which, if unrestricted, would continue to command a high price for development. The greatest obstacle to really effective planning has unquestionably been the fear on the part of planning authorities of incurring indefinite liabilities in the matter of compensation, if the extreme step of forbidding development is taken. Compensation has, in fact, to be paid for individual loss of land values which have not been destroyed but which have only shifted to other land, and where there are a number of owners, the aggregate of values claimable by individual owners when separately assessed greatly exceeds the real loss of the claimants taken as a group.

In regard to developed land and principles of compensation, the Committee enunciates five propositions. (1) Ownership of land does not carry with it an unqualified right of user. (2) Restrictions based on the duties of neighbourliness may be imposed without involving the conception that the landowner is being deprived of any property or interest. (3) Such restrictions can be imposed without liability to pay compensation. (4) The point may be reached when the restrictions imposed extend beyond the obligations of neighbourliness. (5) At this stage the restrictions become equivalent to an expropriation of a proprietary right or interest and therefore should carry a right to compensation as such.

The main conclusions of the Committee on the problem of betterment and compensation are summarized as follows: The present statutory provisions would be altogether inadequate for application to the circumstances created by planning conceived as a national operation. The existence of the compensation-betterment problem can be traced to two root causes: the fact that land in private ownership is a marketable commodity with varying values according to location and the purposes for which it is capable of use, and that land is held by many owners whose individual interests lie in putting their own particular piece of land to the most profitable use for which they can find a market, whereas the need of the State and of the community is to ensure the best use of all land of the country irrespective of financial return. The compensation difficulty is acute in the sphere of developmental value, whether it refers to land already developed by building, as in urban areas, or to land suitable for development in the predictable future, as in fringe land around towns and cities. Development values as a whole depend on the economic factors that determine the quantum of development of various types required throughout the country, and as planning does not reduce this quantum, it does not destroy land values but merely redistributes them over a different area. In theory, compensation and betterment should therefore balance each other. In practice they do not. The present statutory code is limited in operation and is not designed to secure balance, and the Committee is convinced that within the framework of the existing system of land ownership it is not possible to devise any scheme for making the principle of balance effective. A measure of unification of existing rights in land is necessary to overcome the effect of shifting value and to eliminate the conflict between private and public interest.

The Committee stresses first that its recommendations should provide a permanent solution; secondly, that they should not be such as to result in the taking over of property by the State without fair compensation; thirdly, that they should, so far as possible, be capable of immediate adoption, be administratively practicable and not entail greater financial operations than are likely to be feasible during the War or in the early post-war period; and lastly, that they should not be such as to interfere unduly with the economic life of the country or with individual enterprise. On this basis the idea of unification by private pooling schemes or by nationalization is rejected. Instead, the Committee recommends the immediate vesting in the State of the rights of development in all land lying outside built-up areas (subject to certain exceptions) on payment of fair compensation, such vesting to be secured by the imposition of a prohibition against development otherwise than with the consent of the State, accompanied by the grant of compulsory powers of acquiring the land itself when wanted for public purposes or approved private development. As regards built-up areas, it is recommended that public authorities be given powers of purchase much wider and simpler in operation than under existing legislation. Further, a scheme for the imposition of a periodic levy on increases in annual site value, with the object of securing such betterment for the community, as and when it is realized, is suggested.

These recommendations, taken as a whole, form a scheme which is considered workable. They are accompanied by other recommendations relating to the provision of new procedure and simplifications in existing procedure for obtaining and exercising compulsory powers of acquisition, and the ascertainment of compensation on compulsory acquisition. They include the suggestion of imposition of a 'life' on non-conforming buildings; it is suggested that the arbitrator shall assume that buildings which, although not unfit for human habitation, are, by reason of their age, design, construction, arrangement or density, not in accordance with modern standards, will be incapable of use at or before the expiration of ten years. In regard to the central planning authority, the Committee suggests a Minister of National Development, to whom the planning functions of the Minister or Works and Planning should be transferred, who would be responsible for preparing the schemes required to carry out the broad principles of policy determined by a committee of Ministers over which he would preside. He would also be responsible for the control of the developmental rights scheme and the exercise of the powers arising under it, and would be free from departmental responsibilities, but would be assisted by a highly qualified staff. A Commission on the lines of the War Damage Commission, with a full-time chairman and including a member of the economic staff of the Minister, is suggested to secure the proper handling of day-to-day administration and that local authorities, private developers and landowners have ready access to informed advice and authoritative direction.

Such is the bare outline of the scheme and of the argument and principles upon which it is based. The three fundamental principles are unexceptional and are not novel. They have their roots deep in the history of British thought about the land, but for the first time they are here woven into a single pattern for the utilization of the land in the national interest. The lucid analysis with which they are supported should command widespread approval; for there is clear evidence of the forward-looking mind and of the desire to provide for change and the adaptation of system and policy to meet definitely ascertained needs.

There can be no doubt as to the opposition which is likely to be aroused to certain of the proposals: the report points unmistakably to the clash between private and national interests which must be resolved if reconstruction and planning on any adequate national scale are to be possible either now or after the War. That is a task which will require the help of all citizens of goodwill and of vision, if only in the task of education. Moreover, in regard to the central planning authority, the report gives us yet another proposal, although the resemblance to that of the Scott report is more real than might at first sight appear. Less emphatically but no less decisively than the Scott Committee, the Uthwatt Committee distinguishes between planning and development, and although the duties of the Central Planning Commission are less explicitly defined by the Uthwatt Committee, it is clear that a similar type of body is envisaged, although the Uthwatt Committee suggests a body of part-time commissioners, as against a mixed body of full-time and part-time commissioners.

The exact form of the machinery to be established, however, should present no real difficulty now that the problem has been so firmly delineated, the questions to be asked clarified and the principles upon which a solution must be based enunciated with precision and prescience. Already it is clear that the Uthwatt Committee has produced a really outstanding State paper, which will be memorable, both for its intrinsic qualities and for the test it will provide of the capacity of democratic institutions to shape themselves and society to serve the needs of a new age.

A VETERINARY EDUCATIONAL TRUST

IN his speech at the Mansion House recently, at the luncheon held in the course of the congress of the National Veterinary Medical Association of Great Britain and Ireland, Dr. W. R. Wooldridge, the president, announced the formation of a National Veterinary Educational Trust. This development is one that is likely to have a profound influence upon the value of veterinary services in the future and is a result of the increased awareness, within and without the veterinary profession, of the importance of animal health and of the place it must take in the national economy.

This century has seen revolutionary changes in the approach to the maintenance of animal health. At the close of the nineteenth century the development of the Pasteurian concept paved the way for the eradication of certain of the more serious scourges, and for a time achievement in this sphere was mainly concerned with infective processes. The advances made were immense and a new type of veterinarian came into the field, armed with a microscope and trained in the methods of microbial preventive medicine. His achievements were of a high order. Animal diseases that had impeded progress in many countries were brought under control: glanders in Great Britain, rinderpest in South Africa, Texas fever and others are examples of diseases on which successful work was done.

The discovery of vitamins early in this century has led to the realization that these dietary constituents are of great importance to domesticated animals, as they are to man. Later, largely as the result of the start given by South African veterinary workers led by Theiler, certain minerals were found to be indispensable to the life of grazing animals on some types of land. Lack of phosphorus compounds in the pastures had thrown much farm land in South Africa out of production because cattle-farming could not be made profitable, and by the addition of phosphates to the food supply of the cattle the economy of these areas was revolutionized. In addition, calcium, cobalt, copper and other minerals are now known to be essential constituents of the diet of animals and, in many parts of the world, including Great Britain, pastures have been found to lack these elements. The rectification of mineral nutritional deficiency is an important and complex question.

The ravages of parasitic worms infesting livestock have been serious. The life-cycles of many helminths that have been unravelled in recent years are almost unbelievably complex, even to those who know that of the liver fluke; a large number of species of worms is involved, and an extraordinarily wide variety of changes of environment and host is resorted to by different worms in order to ensure a return to a victim of the original species, so that the continuity of the parasite may be maintained. Surely parasitic helminths are the most spendthrift gamblers in existence. Modern intensive grassland husbandry tends to favour the existence of bowel parasites of grazing animals, but fortunately advances in knowledge of the bionomics of parasitic worms, especially during the last two decades, have provided measures that can be used to circumvent the invaders.

To meet the threat of these chemical and biological hazards to the health of our economic animals, extensive knowledge of all the factors involved is required, and the veterinarian is the key link in the chain necessary for the application of the counter-measures.

Chemotherapy for worm infestation and for diseases caused by Protozoa, and, nowadays, even for the control of certain types of bacterial infection, is used on a tremendous scale on animals. Here again the veterinarian is a key man.

The outlook has changed from consideration of the requisite bottle of medicine for treatment of the individual case after illness has become apparent, to the design of measures for application to the animals as a whole, so that disease may be prevented. The name 'veterinary surgeon' almost indicates too accurately the function of the older type of practitioner, compared with that of the modern veterinarian.

Changing agricultural practice has introduced different and new animal disease problems. Foodstuff economies, increased transportation facilities for animal produce and the increased speed of transport between countries have all been contributing factors in these dangers inherent in modern farming. Diseases occur now on farms in Great Britain that were unheard of a generation ago, and not because they were unrecognized previously. Certain metabolic diseases are examples of this trend. The food supply of modern nations demands greater use of high-quality animal products than in the past, and these demands will be intensified in the future. In the absence of adequate supplies of certain of these foodstuffs, human health is menaced, and much active disease in human beings is caused if disease germs are allowed to be present in animal foodstuffs when they reach the consumer. These dangers to human health are, of course, even greater during war-time than in peace. Here again are examples of problems with which the veterinarian must be prepared to deal.

In his presidential address to the National Veterinary Medical Association, Dr. Wooldridge elaborated in some detail his ideas of the manner in which animal disease should be prevented and controlled in the future. He advocated the formation of an Animal Health Corporation, with governors appointed by the State and with powers akin to those of the British Broadcasting Corporation, policy being decided by the Government, but the Corporation having great freedom in the direction of its execution. This Corporation would be responsible for the activities of a complex staff, including specialists in the several branches of the work, practitioners to do the work on the farms, research workers, and a service to ensure that foodstuffs of animal origin are of the necessary quality and free from danger to the human consumer.

Those responsible for policy realize that the future veterinarian must have the best possible mental equipment if he is to play his part. Governments have done much to provide the necessary training, but Great Britain has lagged seriously behind others in this respect, though some improvement has been made during recent years. It is felt that something more is required for higher veterinary education than can be provided from Government sources and, indeed, that public provision additional to Government subsidy is advisable, so that instruction on the widest possible basis free from official control may be available.

The National Veterinary Educational Trust now announced is intended to provide the finances for the extension of the educational organization. An influential board of directors to manage the Trust has been appointed, and it is estimated that a minimum of £1,000,000 will be required. Government departments support the aims of the Trust, and it is anticipated that the necessary funds will be forthcoming.

The Trust would provide scholarships to enable deserving students to become veterinary surgeons, and fellowships and studentships so that those who have graduated may pursue courses of study, or undertake research at home or abroad. Equally, grants would be made to enable graduates aspiring to become veterinary teachers to undertake the necessary post-graduate research, and to assist veterinary surgeons in general practice to take refresher courses. On the other hand, every effort would be made to improve the standard of teaching at veterinary schools and increase liaison with the universities.

The formation of an Animal Health Organization, backed by an active and well-financed Veterinary Educational Trust, such as are envisaged in these proposals, would bring together veterinarians and other workers in many fields bordering on their subject and would give a much-needed stimulus to veterinary studies in Great Britain.

ADMINISTRATIVE EVOLUTION: SERVICE OR TYRANNY?

The Managerial Revolution

Or What is Happening in the World Now. By James Burnham. Pp. iv+271. (London: Putnam and Co., Ltd., 1942.) 7*s*. 6*d*. net.

THE increasing importance of the scientific or technical worker in industry was the theme of one of the most suggestive chapters in Prof. A. M. Carr-Saunders and Mr. P. A. Wilson's study of the professions. Despite, however, all the attention being directed to scientific management, whether through the work of the Institute of Public Administration or the Institute of Industrial Management, the social consequences and implications of the assumption by the technical and scientific staffs of an increasing degree of responsibility for the larger industrial units characteristic of to-day have attracted little attention. Prof. Carr-Saunders and Mr. Wilson's observations, like Mr. S. W. Smith's subsequent paper on the place and function of the administrative and technical worker in the new forms of economic structure, presented at the British Association meeting in 1936, have largely escaped comment. Certainly none of the professional associations of technical or scientific workers appears to have initiated any action to meet the developments and needs thus forecast.

There would be little dissent to-day from the view that organization is a technical problem and that the administration and management of any enterprise must be governed by these few fundamental principles of organization which have been laid bare by the work of Taylor, Fayol, Follett, Dennison, and others in this field. If those are neglected, only inefficiency and confusion can result. A large proportion of our mistakes in the conduct of the War, whether in the field of major policy and strategy or in production, can be traced to disregard of such principles and failure to use the appropriate techniques to serve our ends. The charge has been levelled and established no less against the Civil Service and the Government machine itself than against business and industrial undertakings.

Painful experience clearly enforces the lesson that whether or not administration and management are arts, they cannot be efficient without some use of scientific method and techniques, and the application of established scientific principles. That recognition lies behind all the suggestions advanced from time to time in recent years for a staff college for industry or for the Civil Service, and behind the growing attention which is being given to the training and selection of the men destined to fill the highest positions in industry or the State. Whether or not the administrator of the highest class is born and not made, there is a technique he needs to acquire and an experience which can be thus put at his disposal as an aid, if not a basis, for the skilful selection of the appropriate tool—a scientific technique or some other instrument—which is the essence of an art. The prime qualification for a high administrative position must be administrative capacity, coupling with that the high moral qualities which go to ensure its use with vision, with energy and with courage. Financial, political or social qualifications are secondary or irrelevant factors.

The implications of this change have yet fully to be appreciated. Inevitably as administrative positions come to be filled on grounds of administrative merit, itself dependent to an important extent on professional training and experience, the professional spirit and outlook must influence the policy and conduct of administration whether of industry, of the public utility corporation or of the Government department or local authority. The quality of the administrator and his outlook are far more vital factors in determining the character and efficiency of a public service than its political structure, at least to the extent that without technically competent and upright administrators, no system, from nationalization to the private corporation, will ensure that a really efficient service is rendered. In considering the new forms of organizations to be developed to ensure a right balance between State control and private initiative in reconstruction, we would do well to remember the crucial importance of this factor.

Mr. James Burnham's book gives a new perspective to the problem. He attacks boldly the thesis that socialism is the necessary alternative to capitalism, and while insisting that capitalism is already disappearing, argues that it is being replaced by a new society in which the managerial class has superseded the old capitalist. This process, he argues, is already proceeding. The extension of Government ownership and control means a continuous increase of managerial dominance in the economy as a whole. Every new incursion of Government into the economy means that one more section of the economy is wholly or partly removed from the reign of capitalist economic relations.

Mr. Burnham points out, what so many of the more ardent protagonists of a return to *laisser-faire* and the pre-war chaos in Great Britain fail to perceive, that this process is not being implemented by the Civil Servant type of bureaucrat against whom their propaganda is directed. The new controls are and must be administered by managers of the same type and training as those who are responsible for the management and direction of industry. The position, role and function of the managers depend upon the technical nature of the process of modern production, and the managers of whom he writes tend to think of solving social and political problems as they coordinate and organize the actual process of production. Moreover, arguing that the instruments of production are the seat of social domination and that who controls them, in fact if not in name, controls society, because they are the means whereby society lives, he points out that this social transition leading to the social dominance of the managers may be a corporate dominance, the managers deriving their superior rights and position not as individuals but through their functional status and the actual directing responsibilities which they discharge. Through the possession of privilege, power and command of educational facilities, they will be able to control, within limits, the personnel of the managerial recruits, and the ruling class of managers will thus achieve a certain continuity from generation to generation.

An economic structure based upon State ownership of the major instruments of production provides the framework for the social domination of the managers. It is the only economic structure through which that social domination can be consolidated, and Mr. Burnham does not conceal the fact that such an economy may, though not necessarily, provide the basis for domination and exploitation by a ruling class of an extremity and absoluteness never before known. That warning is reinforced by his exposition of developments in Germany and in the U.S.S.R. as stages in this managerial revolution and his review of the position in the United States, where he insists the New Deal has accelerated the move towards a managerial society.

It is not necessary to accept all Mr. Burnham's interpretation of recent history in Germany and in the U.S.S.R. or even in the United States—and his theory scarcely appears to be entirely viable in the former two—to realize that the considerations advanced must be seriously regarded in determining the institutions to be established to serve post-war needs in Great Britain. Conclusions which are not altogether convincing should not lead us to ignore or discount the shrewd observations on which the argument is based—for example, the comparative absence of managers from the forced or voluntary refugees from Nazi Germany.

This outstanding essay on the changing shape of society raises two issues of the utmost fundamental importance. In the first place, the chapter on the economy of managerial society is clearly describing an aspect of planning on which Walter Lippmann launched a brilliant attack in "The Good Society". Under a managerial economy, as described by Mr. Burnham, planning becomes a matter of course, and while such an economy is better placed than capitalist economy to make use of new inventions and technological devices, certain limitations in individual freedom of labour and bargaining, at the least, must be accepted. These are the price to be paid for the stimulus to production and to the more effective planning of the economy as a whole, with all the advantages in a higher material standard of living which are inherent in a managerial economy.

Whether this is too high a price to pay for that greater ability to plan and easier realization of the aims of planning, depends largely on what those aims may be, and Mr. Burnham's assertions as to those aims must be firmly challenged. Here as elsewhere he is far too pessimistic. Scientific humanism may well be far more capable than he admits in giving sound values to a social structure which would otherwise be intolerable. In recognizing the professional solidarity of the managerial class, he discounts too much the influence of the professional ideal and outlook stressed by Prof. Carr-Saunders and Mr. Wilson. Neglect in the past by professional associations of their responsibilities towards society does not warrant the belief that the professional spirit will be displaced so absolutely by self-interest as Mr. Burnham suggests. The evidence is rather the other way; and the conclusion is that we should see that the new privileged class of managers is imbued with the same standards of integrity and loyalty as the Civil Service and with those standards of public duty which have characterized our aristocracy at its best in the past.

This somewhat superficial analysis naturally strengthens the argument of those who, with Walter Lippmann, contend that society should be unplanned because it is difficult to set limits on planning which preserve the essential human liberties. The merit of Mr. Burnham's book, however, lies rather in directing attention to a social phenomenon requiring close examination than in the acuteness of its analysis. This is again apparent in the chapters on the shifting centre of sovereignty and on totalitarianism and managerial society, where a second fundamental issue is raised. To compare these chapters with corresponding passages in Prof. Barker's "Reflections on Government" might be unfair, but demonstrates the shallowness of Mr. Burnham's understanding of the nature and working of democratic institutions. That is the fatal weakness which handicaps his delineation of a solution of the problems which he outlines so suggestively.

Though the U.S.S.R., Germany and Italy, the nations which have advanced furthest towards the managerial social structure, are all at present totalitarian dictatorships, Mr. Burnham holds that with the consolidation of the structure of managerial society, its dictatorial phase will change into a democratic society. He considers that certain aspects of a democratic society favour the more efficient functioning of managerial society; on this point Mr. R. B. McCallum's valuable article on the "Future of Information Services" in a recent issue of *Agenda* is highly pertinent. But Mr. Burnham fails to see how democratic institutions can be used to define the objectives of planning policy, for example, and to exercise that control over the managers which will ensure that they serve the ends of society and not society those of the managers. Under a managerial society all major parts of the economy will be planned and controlled by a single integrated set of institutions, but while he sees clearly that a one-party State is incompatible with democracy, he misses the whole idea of the evolution of new social controls on which Mannheim lays such stress in the planning for freedom.

Mr. Burnham has written a provocative book over which scientific workers may well ponder, though undismayed by its pessimism and the rather gloomy tones of the picture it portrays. The problem is set forth fairly enough: Who shall control the planners and how? The necessity for a wider planning of the major aspects of social and economic activity in the broadest sense is inescapable. The problems we have to face are those of defining the objectives and elaborating the social controls required to reconcile planning with the retention of those essential human liberties without which the human spirit droops to slavery. It is unthinkable, however, that professional men, and above all men of science who have so large a part to play in that planning, will not bring to their task a spirit no less generous and disinterested than they have brought to the quest for truth, or that their professional solidarity, whatever may have been its temporary shortcomings or aberrations, will not remain unshakably loyal to that tradition of service and integrity to which the professions owe alike their essential inspiration and vitality.

R. BRIGHTMAN.

SCIENCE AND CURRICULUM REFORM

Science and Education

By S. R. Humby and Dr. E. J. F. James. (Current Problems, No. 15.) Pp. ix+146. (Cambridge: At the University Press, 1942.) 3*s*. 6*d*. net.

OUR educational system no longer serves adequately our needs or aspirations and, under the stress of events which help to reveal its shortcomings, the outlines of a new policy are being hammered out. In the discussions that are taking place, the field of curriculum reform has been somewhat neglected. Yet here, too, changes are very obviously necessary: the anachronistic curriculum of our secondary schools, for example, not only lacks coherence and unity but also is largely irrelevant to the needs of the future citizens of an industrial democracy. A course of study suited to such a society would be centred on the social and natural sciences. Traditionally, however, the aim of the secondary school is the somewhat vague one of developing in its pupils an appreciation of literary culture. Consequently, linguistic studies secure the lion's share of the time available. The result is not only a loss of industrial efficiency but also a lack of grip on the part of administrators trained to think in categories irrelevant to many of the situations they meet, and called upon to deal with forces they can neither understand nor control.

These are some of the problems discussed in a short but important book by two science masters at Winchester. Their first chapter, on "Science and Society", is devoted to an exposition of views not unlike those propounded by Prof. Bernal, Dr. Lovell and others. The authors conclude that much more could be done to make available to all the fruits of science if one could bring about a new outlook through an improved education. "Civilisation is unaware both of the extent to which it has been modified by scientific discovery in the past and of the potentialities that extended and co-ordinated research open for the future . . . this lack of awareness has its origins in our educational system . . . [Many] educated men and women remain resolutely unaware of the way in which [scientific] discovery . . . might revolutionise society in the future". One wonders whether, in fact, the problems can be solved merely by teaching people the right things. Such optimistic views were common in the eighteenth century, but are they correct ? The use of the word "resolutely" in the passage quoted is significant.

In their second chapter, the authors describe in a brief but highly interesting way the history of science teaching. They remind us of the struggles made, all through the nineteenth century, by enlightened individuals and by Government commissions, to introduce scientific education into schools. The compromise achieved as a result of all these efforts is, of course, familiar. So far as possible, the old framework was preserved, but a minor place was made for science, which was given a time-allowance too small for average pupils but just sufficient to awaken the interest of a few brilliant and specially gifted boys. At the same time, technical education was provided—that is, a system was specially devised to serve the bare needs of industry. Thus, technicians and men of science were provided in fair number, but the rich cultural possibilities of a full scientific education were left largely unexplored. Incidentally, the still-born Spens Report favoured the extension of this unsatisfactory solution.

From the whole of this disturbing story, the authors conclude that, "the present faulty relationship between science and social needs is primarily an educational problem, and the first steps to its solution must be taken in the schools and universities". This may well be so, and it is certain that social and educational problems are interrelated. At the same time, one wonders uncomfortably whether, in this proposition, the cart has been put before the horse. Can changes in education precede and initiate social changes ? Can there be an educational system which accepts and pursues values different from or opposed to those accepted by the community it serves ? Are not the most powerful and influential groups in society averse to change ? Is it just accidental—merely the result of ignorance—that the literary and not the scientific studies play the paramount part in education ? On all such points sociologists have interesting things to say.

The remaining three chapters of Mr. Humby and Dr. James's book are devoted to matters of smaller but more immediate importance—to "The Content of Science Courses", to "Problems of Presentation" and to "The Teaching of Scientific Method". The authors are distinguished teachers of considerable experience and they have many wise and cogent things to say—on general science, on practical work, on quantitative experiments, on the uses of the history of science and so on.

Their book is short and the task of selecting topics for discussion must have been a very difficult one. Yet a few omissions should be noted, since one has the feeling that consideration of them might have served to modify, in detail though probably not in principle, some of the conclusions reached. Thus, one wishes they had discussed the place of biology, a subject particularly suited to schools. Again, it might have been profitable to take into account the possible uses of radio and cinema: these new media are likely in time to have a tremendous effect both on the content of science courses and on the methods of teaching it. Perhaps, too, the authors might have taken note of the highly important work on the technique of examinations done in Chicago by Prof. Tyler and his school. These workers have devised ingenious methods of evaluating the progress made by learners in developing scientific attitudes and in mastering the scientific method. Lastly, it would have been interesting and useful to read a critique of the proposals made by the Progressive Education Association. The course of science education proposed by the Curriculum Commission of that Association is based on a large-scale research by sociologists, psychologists and educators, it has been well tried in practice, and it represents the most scientific attempt at curriculum reform so far made.

To complain about such omissions in a book which one has greatly enjoyed reading and from which one has learned much may seem ungracious; it will, I hope, be taken chiefly as a request for more. The book as it stands, though short and condensed, is a real and valuable contribution to the solution of urgent educational problems. One hopes it will be widely read and studied. Teachers in universities and colleges will find here in outline a description of what the best teachers in secondary schools are trying to achieve; and teachers in secondary schools would undoubtedly gain much from the helpful and stimulating discussion of problems they constantly encounter.

J. A. LAUWERYS.

TITRATION EXPLAINED

Volumetric Analysis

By Prof. I. M. Kolthoff and V. A. Stenger. Second revised edition. Vol. 1: Theoretical Fundamentals. Pp. xv+309. (New York: Interscience Publishers, Inc.; London: Imperia Book Co., Ltd., 1942.) 4.50 dollars.

THIS is an instance of a magic carpet, though we suspect it was really a steamer, which has transplanted a professor and his book from Europe to the Americas, the language changing during the process from German to Anglo-Saxon. The original German work was published in 1927 and translated for publication in New York by Prof. Furman. Prof. Kolthoff now has the collaboration of Dr. Stenger, a chemist employed in industry. This is a significant indication of the alliance between theory and practice which is so marked a feature of American science.

No book has had more influence in developing the understanding of chemical reactions than Wilhelm Ostwald's "Theoretical Foundation of Analytical Chemistry", published in 1894. Until then analytical chemistry and its development was mainly empirical, and though this must still be partially necessary in a subject which has a practical goal, it is to-day accepted that with the aid of theoretical information it is possible both to improve existing methods and to devise new ones.

This statement is particularly true of volumetric analysis, a branch which has become of increasing importance. The progress of an experimental investigation often depends on the ability to make measurements in large numbers which in turn means, quickly. Weighing is too slow, whereas titration can be quick. Hence the urge to develop it, especially by biochemical investigators; at first speed is more essential than great accuracy, but eventually greater exactitude is required. A distinction can be drawn between the methodic or technical errors and the intrinsic errors based on the chemical reaction in volumetric analysis. The methodic errors are due to imperfections in measuring apparatus and technique and in the human factors; such errors affect the reproducibility of a titration and can be treated statistically if enough determinations are made.

This is Volume 1 of the work and treats the theory of volumetric analysis apart from the practice; there is division into ten chapters. One of the most valuable of these relates to indicators of which to-day there are a goodly number, which are grouped under three headings: (1) for acid-base reactions; (2) for precipitation reactions; (3) for oxidation-reduction reactions. The last group is of considerable interest to-day and is considered at some length in the book.

The book is clearly written having regard to the complexity of the subject; and now that we all have a considerable knowledge of physical chemistry should assist those, particularly biochemists, who seek to use volumetric methods. It contains some useful data in an appendix.

E. F. A.

MARRIAGE CUSTOMS IN THE MAKING

Marriage and Family in Mysore

By M. N. Srinivas. Pp. iv+218. (Bombay: New Book Co., 1942.) 7.8 rupees.

MR. SRINIVAS, writing with the valuable equipment of a sympathetic understanding of Hinduism and of the traditional values expressed in the customs of Mysore related to the family, and appreciating, with the objective view of the anthropologist, its social structure, has presented readers with a valuable study. The picture of the attitude to marriage current in a Hindu community to-day shows the trend of changing customs. One would welcome similar studies of different communities made by those belonging to the tradition of the communities studied, equipped with a scientifically trained mind and a wide knowledge of functional anthropology and social psychology. A group of such studies would throw much-needed light on the evolution of the family, and might well disclose a recognizable pattern of development, thereby proving a valuable guide to the social biologist.

While acknowledging his indebtedness to Westermarck, and his appreciation of the work in Mysore of Ananthakrishna Iyer, Mr. Srinivas does not hesitate to challenge both in their interpretation of certain Kannaka customs, particularly 'bride-price', 'marriage by capture' and an assumed earlier matrilineal social structure, I think, with some justification.

The author's first-hand knowledge of local practice in many instances clarifies the position. Take, for example, the complicated customs grouped under the term 'bride-price'. The two conflicting ideas—each forming part of the protracted marriage ceremony—of payment for the bride (twice as much for a virgin as for a widow) and of the free gift of the daughter by the father are expressed in the marriage rites. 'Evidence is available to prove that 'bride-price' once prevailed in every caste and region of Dravidian India" (p. 20). Brahmans as well as non-Brahmans practised it, and up to fifty years ago girls were frequently sold among the Brahmans for sums ranging from R. 300 upwards. On the other hand, the representatives of a group of Brahmans signed an agreement in the Saka year 1347 "to the effect that henceforth the father had to give his daughter to the bridegroom gratuitously. Both the father who accepted money and the bridegroom who paid money for the bride should be subject to punishment by the king and excommunication from their caste." The lower castes tend to copy the customs and ceremonies of the Brahmans; new customs, often conflicting with those that were indigenous, were adopted from invading peoples. This is seen in the wide variation in marriage restrictions, exogamy of various kinds and degrees. One of these restrictions—'gotra exogamy'—is rigidly observed by Brahmans even to-day. "In the desire to elevate their social status many non-Brahman castes have recently acquired 'gotra' (ancestor groups). This shows that a decadent institution may acquire a new prestige through it being made the symbol of a new superiority. This tendency, unfortunately, appears to apply to the re-marriage of widows. While the educated Brahmans are beginning to relax the restrictions on re-marriage, sub-castes that previously permitted the marriage of widows are now prohibiting them in emulation of the customs of the higher social groups" (p. 126).

Both Brahmans and non-Brahmans agree in prohibiting the marriage of cousins, but among the educated to-day the restrictions are applying less and less to 'cross-cousins'.

One would like to know more of the trends and influences being derived from the impact of Western thought. In Mysore, among the indigenous groups the author notes a new one "called the 'London Party' formed from descendants of those who dared to cross the sea". They were boycotted at first, but being rich and influential this fashion passed; now "in all the sub-castes an England-returned bridegroom is sought after, highly bid for, and the girl who buys him is considered lucky".

In some of the customs quoted, there is opportunity for comparative study which should prove fruitful. For example, in one tribe that migrated to Mysore from Northern India, as part of the marriage ceremonies the girl has to weep and show resistance. Rejecting the 'marriage by capture' origin of the custom, the author postulates three possible explanations: the bride's reluctance to leave her parents, or that weeping at the wedding prevents misery later, or the resistance symbolizes the sexual frigidity of the woman. It is interesting that in Albania some thirty years ago, it was the custom of the Moslem bride, dressed in her wedding finery (and the practice was copied by the local Christians), to weep for two days before the wedding.

The book is commended to those concerned with the place of marriage and the family in the community as a thought-provoking study. The influence of any social ambitions and current values in the emphasis given to religious sanctions indicates the way in which changes in interpretation and practice may come about. For an adequate understanding of the problems involved the help of the psychologist as well as the anthropologist is essential.

S. Neville-Rolfe.

ENTOMOLOGY CONDENSED

Outlines of Entomology

By Dr. A. D. Imms. Pp. vii+184. (London: Methuen and Co., Ltd., 1942.) 12*s*. 6*d*. net.

THERE was a time, perhaps it is not entirely past, when entomology was among the least of the biological sciences; when the cockroach was held to epitomize the class; and when a specialist on the

Ctenophora might be credited with a knowledge of zoology, but scarcely a specialist on the Insecta. Yet insects have provided the material for most of the biological theory of the past fifty years: sex determination, biological races and species formation, mutation and heredity, bioluminescence, mechanisms of behaviour, biological oxidations, the inheritance of acquired characters, adaptive coloration, theories of population, the physiological action of genes—these are a few of the subjects which owe much to the diversity of insects and the unrivalled opportunities they offer for studying the workings of the living organism. The utilization of this material in many fields of physiology and biochemistry has scarcely begun. Much of insect physiology still consists in confirming upon insects what is already known from studies of higher animals. But the tissues of insects are so accessible, and experiments can be made upon them with such facility, as to encourage the hope that there are many more fundamental problems in biology the analysis of which may be pressed further and with greater ease upon insects than upon other forms.

At the same time insect pests constitute an ever-present threat to the health of man and animals and to our supplies of food and raw materials; a threat which is not diminished in time of war. The work of those who combat harmful insects rests upon an elaborate foundation of insect systematics, ecology and physiology. The applied entomologist to-day demands ever-greater refinements in taxonomy. Taxonomy pressed to the limit is apt to transcend the powers of the museum worker and become a matter of biological races whose distinguishing characters can be recognized only in the field by studies in ecology. At every turn the ecologist and the applied entomologist are confronted with problems in physiology.

To unify this subject and to present it as a whole with proper emphasis on all its several parts is a task that demands experience and judgment. Dr. Imms placed entomologists the world over in his debt by the production nearly twenty years ago of his "General Textbook of Entomology". He has now attempted the formidable task of condensing the essence of his subject into a book of 184 pages. It may be said at once that he has succeeded to a remarkable degree. The book falls into two equal parts: anatomy, physiology and development; and nomenclature, classification and affinities. In both parts the allocation of space and the quantity of detail given have been decided with very sound judgment. It is an austere book "intended for anyone who is willing to take sufficient pains to acquire an elementary knowledge of entomology as a branch of general zoology", and it makes no concessions to those who like to escape technical terms. The whole of terminology is here, sometimes in such concentrated form that concentration will be needed also by the student. But the presentation is uniformly excellent.

On the physiological side (the descriptions of function fit in naturally with those of structure) the point of view of recent surveys is adopted. This marks a distinct change from the "General Textbook" in which the presentation, apart from the inclusion of some recent work, has remained substantially that adopted by Packard. In a book so concise as this, there are, of course, physiological allusions which the first-year student for whom the book is intended would probably not understand. But if he is driven to seek information elsewhere they will have served a useful purpose.

In a book so well planned and indexed and so free from errors of typography and fact it is difficult to make constructive criticisms. But since controversy is the stuff of science, one might challenge the justification for the term 'prepupa' (p. 92). Moulting in any insect at any stage is necessarily preceded by some degree of quiescence and by some change in outward form determined by the changes in the new instar. When the new instar is markedly different the period of quiescence and the outward changes are more in evidence. It is difficult to see the value of calling this period a prepupal instar.

The second half of the book in which the characters and mode of life of all the orders of insects are summarized is remarkably well done, though the descriptions are necessarily very brief. This part is lightened by a series of 'appendixes' on more general questions: an account of the phase theory follows the section on Orthoptera; a review of 'fecundity and biological equilibrium' follows the Homoptera. Other examples are 'insect colours' after Lepidoptera; 'aquatic insects' after Coleoptera; 'social insects' after Hymenoptera; 'parasitism' after Diptera. All these are good.

The book as a whole challenges comparison with Weber's "Grundriss der Insektenkunde", likewise written as a student's introduction to a larger work. The excellent illustrations of Dr. Imms's book have not the dramatic quality of Weber's. But as befits an English book the essence of the subject has been distilled into a much smaller compass, and the student who takes Dr. Imms's "Outlines" as his first guide to serious entomology will have started well.

V. B. WIGGLESWORTH.

A NATURE DIARY

Wild Life through the Year

By Richard Morse. (Black's Nature Pocket Books.) Pp. 158 (58 plates). (London: Adam and Charles Black, Ltd., 1942.) 7*s*. 6*d*. net.

RICHARD MORSE in this attractive book takes us with him through each month of the year. The author in his preface hopes that readers of this book may be induced to keep Nature diaries of their own—an admirable suggestion and one which gains rather than loses its force in these grim days. Mr. Morse tells us when to watch for the spring bird migrants and when to be on the look-out for the early flowers and butterflies. The book will be a help to many who love Nature but are in need of a clear and simple guide.

I should say that April rather than March is the puffins' month (p. 28) for arrival at their nesting stations; the puffin is at least a month later than either the razorbill or the guillemot. When Mr Morse gives March as the month in which the red deer casts his antlers he is perhaps referring to the park stags of England; the Highland stag rarely casts his horns until April, and sometimes not until May. In his account of the autumn breeding of mammals, the author might perhaps have mentioned the Atlantic seal, which has its baby in September October, or even November.

The book is illustrated by a number of good photographs, and there is an interesting series of twelve whole-page line drawings, the art of Miss Doris Meyer. It makes a good Christmas gift and deserves a wide circulation.

SETON GORDON.

Elementary Mathematics

By Prof. Hyman Levy. (Nelson's Aeroscience Manuals.) Pp. 216.

Modern Trigonometry

By M. J. G. Hearley. (Nelson's Aeroscience Manuals.) Pp. 168.

(London and Edinburgh: Thomas Nelson and Sons, Ltd., 1942.) 5*s*. net each.

THE utilitarian aspect of mathematics has been well emphasized in the declaration that "Mathematics is ever ready to serve, and it rules because it serves". The present conflict has undoubtedly called forth no inconsiderable development of the practical nature of the subject. As a consequence, quite a number of books have been issued, mainly for use in Service training.

There is no short cut to the realm of mathematical knowledge and skill, but the long road may be traversed more quickly and easily if the traveller's interest is vitally stimulated. In the two books under notice, this aim has been commendably attained. The volumes belong to a series designed to cover the field of science underlying the principles of aeronautics.

As would be expected, Prof. Levy's "Elementary Mathematics" is an inspiring tonic. In its seventeen chapters, the reader is led from first principles right into the heart of the subject by simple logical steps which are so attractively presented that the student is not only making useful progress, but also is amazed to find eventually what a practically interesting subject this alleged abstruse and meaningless mathematics really is! He becomes familiar with the varieties of number, including vectors; with the fundamental facts of geometry and algebra; with the conception of a function and the basic ideas underlying the calculus. He is also taught to 'calculate' properly, with or without logarithms, tables of which are provided. It is indeed quite probable that the sincere reader will, like the famous character of Dickens, ask for more!

Mr. Hearley's "Modern Trigonometry" is designed to provide a fresh and interesting introduction to the subject. The practical nature of trigonometry is well developed by the inclusion of so many applications, and not only these, but also the attractive presentation of the text, reveal how well the aim has been carried out. The student will appreciate here the fundamental part of trigonometry in navigation and modern engineering. Besides answers to the exercises, the necessary tables are provided.

F. G. W. BROWN.

Chemical Industries

Chemical and Physical Data, Chemical Engineering, Glossaries of Industrial Chemicals, Pharmaceuticals, Constructional Materials, Perfumery Raw Materials, Directory of Plants and Materials. Edited by L. Ivanovszky. Sixteenth edition, largely rewritten and revised. Pp. 338. (London: Leonard Hill, Ltd., 1942.) 15*s*.

THIS is one of those books that everyone dealing with chemicals likes to have on his desk. It begins properly with the index so that we can find the information required, and is divided into sections dealing with constructional materials, power plant and water treatment, chemical plant, handling, conveying and transport, instruments and apparatus. Finally, there is much information about industrial and fine chemicals, including a glossary of trade-names.

The advertisements of the firms prepared to supply all our requirements come boldly after each section, as they do on the front pages of the daily papers, instead of being hidden away at the back.

It is one of those books which, when we have become used to it, makes us wonder how we have done without it previously: it is hoped to make it an annual publication.

It is noted in the preface that Prof. D. M. Newitt, who has been associated with the preparation of the volume since the first edition, has now ceased to take any active part.

Science Looks Ahead

By Prof. A. M. Low; with Contributions by Dr. Julian Huxley, C. G. Grey, G. E. T. Eyston, F. Kingdon Ward, Dr. H. Spencer Jones, Sir Alliott Verdon-Roe. Pp. 640+47 plates. (London, New York and Toronto: Oxford University Press, 1942.) 12*s*. 6*d*. net.

PROF. A. M. Low is well known for his presentation of scientific and technical advances in popular terms. In the present volume, he has attempted a survey in descriptive terms of recent developments in many fields. In successive chapters he discusses sources of power, rays, science and war, materials of industry, transport, measurement, medicine, the sea, exploration of the universe, weather, communications, exploration, the cinema, and science and the criminal. Dr. Julian Huxley provides a chapter on evolution, Dr. H. Spencer Jones one on the planets, and Capt. F. Kingdon Ward two on food plants and 'living' fossils respectively; while C. G. Grey deals with aeroplanes in war, Capt. G. E. T. Eyston with speed records and Sir Alliott Verdon-Roe with flying. The forty-seven plates illustrate outstanding features of the articles they accompany, and there is a useful index.

A History of Tropical Medicine

Based on the Fitzpatrick Lectures delivered before the Royal College of Physicians of London, 1937–38. By Sir H. Harold Scott. Second impression. Vol. 1. Pp. xix+648+3 plates. Vol. 2. Pp. iv+649–1219+ plates 4–13. (London: Edward Arnold and Co., Ltd., 1942.) 63*s*. net.

THIS is the second edition of a book which was first published so recently as 1939 and reviewed in NATURE of November 11, 1939, p. 801. Volume 1 deals first of all with the history of tropical medicine in the navy and mercantile marine, the army, the Colonies, Protectorates and Dominions, India and Australia. It then proceeds to a consideration of the history of malaria, blackwater fever, yellow fever, trypanosomiasis, leishmaniasis and leprosy. Volume 2 continues with diseases, namely, cholera, plague, undulant fever, relapsing fever, meloidosis, dengue, amœbic dysentery, hepatitis, ankylostomiasis and tropical diseases connected with food. Some special areas, namely, the Suez and Panama Canals, are then reviewed, and the diseases connected with the slave trade are considered. Fifteen biographies are appended, and the book ends with a bibliography, appendix and author and subject indexes.

BLAISE PASCAL (1623-1662)

TERCENTENARY OF THE CALCULATING MACHINE*

By Prof. S. CHAPMAN, F.R.S.

THE production of the first calculating machine was important in itself, and still more because it started the progress towards the many intricate and powerful computing machines now available. But the inventor was far greater than this invention.

Pascal's life was short, and clouded by much illness; he died at the age of thirty-nine. But his achievements were so varied and remarkable that he has become the subject of an extensive literature, ever growing as each age interprets him anew. In the words of T. S. Eliot, the history of men's opinions of Pascal, and of other men of his stature, is a part of the history of humanity.

What were Pascal's achievements, and what manner of man was he? He was a mathematician and geometer, who at the age of sixteen made the first great advance in synthetic geometry since remote antiquity; by his famous theorem on a hexagon inscribed in a conic section he won the recognition of the most learned men of his time. But he was not simply a man of books, pen and paper; he was eminent as an experimental physicist, for his studies on the equilibrium of fluids, on the pressure of the air, and on the creation of a partial vacuum; he also designed the hydraulic press, constructed long afterwards by Bramah. Further, he was a practical inventor, as we specially remember here. He it was who invented the wheelbarrow in its present form; previously there had been hand-carts, like the coster's barrow, but Pascal designed the one-wheeled barrow, and applied the same idea to the sedan chair.

This mathematician, physicist and inventor was well taught by his father in languages and philosophy. Of good family, their home life was one of culture and fine manners, and they were accustomed to the society of the noble and eminent; father and son had much in common.

The father died when Pascal was twenty-eight, and for two years he lived in style, mingling with the men of wealth and position around the court of the Grand Monarch, and sharing many of their pleasures —music, the ballet, the chase, the gaming table, the conversation of women, the fascinating affairs of war and the State. Besides being a good spender of money, Pascal knew how to add to his wealth by business enterprise.

But at thirty he turned from these activities and distractions. Hitherto a faithful Catholic living in the world, he now became deeply concerned with religion, partly through the influence of his younger sister. She, a young woman of great strength and beauty of character, had already entered the religious community of Port-Royal, the centre of a puritan reform movement within the Roman Church, inspired by Jansen, the Bishop of Ypres. A year after these stirrings of deeper feeling, Pascal had an ecstatic religious experience, and for the remaining eight years of his life he was closely linked with the abbey and schools of Port-Royal.

He still lived in his own house, and retained much of his wealth. But he mortified his flesh by an ascetic rigour even beyond that which his physicians imposed to relieve his increasing ill-health. His asceticism, however, like that of St. Francis of Assisi, was accompanied by lovingkindness to others.

Among the vanities of the world which Pascal now renounced were his mathematics and his science. But he did not wholly abandon them. From time to time, through intercourse with such friends as Fermat and Mersenne, and sometimes simply as a distraction from pain, his thoughts returned to these pursuits, in which his mind moved with perfect ease and grace. Almost without effort he made new discoveries in the geometry of the cycloid and in the theory of probability; he even engaged in scientific controversy on questions of priority.

In these last eight years, however, he won new fame as a writer on religion. Strife arose between the Jesuits and the Jansenists. The Jesuits charged the community of Port-Royal with heresy, and the austere Jansenists attacked a Spanish group of Jesuits whose casuistry they regarded as dangerous to morality. Pascal engaged in the controversy, and wrote eighteen letters called the Provincial Letters. French literary critics acclaim these prose writings as of capital importance in the foundation of French classical style. As polemic, says T. S. Eliot, they are unsurpassed, not by Demosthenes, or Cicero, or Swift.

In his last two years, Pascal meditated writing an intellectual defence of Christianity, and made copious notes for it. He died before beginning the actual writing, but these notes were published, after his death, as the famous "Pensées" of Pascal. Even these fragments reveal him as a great literary artist, whose intellectual passion for truth made him utterly dissatisfied without a spiritual explanation of human life. He brought to this work his great powers as a man of science, though he did not, like some scientists, suggest that his own faith was sufficient warrant in itself for Christian belief by the common man. Voltaire and Condorcet might regard Pascal's religious writings as the product of a mind disordered by ill-health, but in these poignant days, so tragic especially for our sister-nation, to which these three great men belonged, Pascal's "Pensées" have a renewed interest, though some of his presuppositions are now shared by few educated men.

Pascal was proudly conscious of his intellectual powers, but he became also profoundly humble as a sinful man before God, and in his last years he was filled with loving concern for the poor. His wish to supply their material needs spurred his practical genius to start a company for putting public vehicles, omnibuses, on the streets of Paris, for the convenience of the people, and to gain profits, no longer for himself, as in his earlier years, but for almshouses and hospitals. These buses were started during the last months of his life, and deeply engaged his attention; they seem to have achieved instant social and commercial success.

Newton, whose birth we celebrate in this tercentenary year, was a greater man of science than Pascal, but I judge Pascal to be the greater man. Newton's thoughts, like Pascal's, turned much to religion in his later years; but he followed dark paths, pondering over the prophetic Scriptures; none but the curious antiquary would to-day read his religious writings. Pascal's, on the other hand, have an abiding attraction both in their substance and their literary form. Newton was a man of virtue and plain living; but Pascal in his later years was a saint. Newton's scientific work, though great in substance, was written in poor Latin. Pascal used his native language in writing both on science and religion, and his works belong to the great treasury of French literature.

---

* Address delivered at a memorial luncheon held in London on October 19.

Pascal's invention of the calculating machine, just three hundred years ago, was made while he was a youth of nineteen. He was spurred to it by seeing the burden of arithmetical labour involved in his father's official work as supervisor of taxes at Rouen. He conceived the idea of doing this work mechanically, and developed a design appropriate for this purpose; showing herein the same combination of pure science and mechanical genius that characterized his whole life. But it was one thing to conceive and design the machine, and another to get it made and put into use. Here were needed those practical gifts that he displayed later in his inventions of the wheelbarrow and the omnibus. He must find and test suitable materials for his machine—iron, copper, ivory, ebony, wood. He must find and indeed train suitable workmen, and settle many points by actual trial. His first model was followed by others, and gradual improvements occupied much of his time for the next ten years, in which he strove indefatigably after perfection. He wished also to obtain due reputation and reward from his invention. He obtained royal protection for it, and gained the patronage of many distinguished men. In 1652 he presented one of the last of his fifty models, with a famous letter, to Queen Christina of Sweden. He also wrote a prospectus of his invention that would do credit to a modern school of salesmanship. But other men, despite the royal patent, pirated his invention; and the sight of one of these copies, "a monster", he said, fair on the outside but valueless in use, so disgusted him that he abandoned further interest in his machine.

In a sense, Pascal's invention was premature, in that the mechanical arts in his time were not sufficiently advanced to enable his machine to be made at an economic price, with the accuracy and strength needed for reasonably long use. This difficulty was not overcome until well on into the nineteenth century, by which time also a renewed stimulus to invention was given by the need for many kinds of calculation more intricate than those considered by Pascal.

Consequently until the present century the principal aid to calculation was the table of logarithms published by their Scottish inventor, Napier, in 1614, put into more practical form by Briggs at about the time of Pascal's birth, and afterwards used also in the slide-rule.

These inventions will always retain great practical value, but where extensive and elaborate calculations are necessary the economic method is to use a suitable computing machine. To-day we recall Pascal as the first originator of such machines.

ECONOMY IN THE USE OF FERRO-ALLOYS*

By DR. W. H. HATFIELD, F.R.S.

IN times of peace, particularly if they are of long duration, the qualities and characteristics of that which is produced are the result of tradition and usage, salesmanship, and the developments due to technical progress based on the application of old or new knowledge. Tradition, usage, and salesmanship slow up in measure with the inevitable progress towards the realistic efficiency possible through knowledge and the consolidation of technical progress. War and preparation for war insist upon stark efficient realism, and those who prepare for war are given more time to attain to it than those who are unexpectedly called upon to face such conditions. Also, in times of peace, international trade throws open to all countries the world's resources in raw materials and facilities on an economic basis; war rudely disturbs this state of things, and realism in production must then deal with a limited or changed availability of that upon which production can continue.

These conditions apply at the moment to the production of steel, and particularly to special and alloy steels. Concerted efforts are being made within the industry to attain maximum efficiency based on the availability and changing availability of raw materials and facilities. It will be obvious that technology and technique so developed can be, and will be, projected with advantage into post-war times.

ELEMENTS OF INTEREST IN STEEL METALLURGY.

Element	Group	Date isolated	Metal isolated by	Nationality
Hydrogen	I	1766	Cavendish	British
Copper	I	Prehistoric		
Zinc	II	Prehistoric		
Aluminium	III	1854	H. St. C. Deville	French
Carbon	IV	Prehistoric		
Silicon	IV	1854	H. St. C. Deville	French
Titanium	IV	1825	Berzelius	Swedish
Zirconium	IV	1824	Berzelius	Swedish
Tin	IV	Prehistoric		
Lead	IV	Prehistoric		
Nitrogen	V	1772	D. Rutherford	British
Phosphorus	V	1669	H. Brand	German
Vanadium	V	1830	Sefstrom	Swedish
Arsenic	V	1240	Albertus Magnus, Bishop of Regensburg	German
Niobium	V	1801	Hatchett	British
Oxygen	VI	1774	Priestley	British
Sulphur	VI	Prehistoric		
Chromium	VI	1798	Vauquelin	French
Selenium	VI	1818	Berzelius	Swedish
Molybdenum	VI	1782	P. J. Hjelm	Swedish
Tungsten	VI	1783	F. D. and H. J. D'Elhuyar	Spanish
Manganese	VII	1774	J. G. Gahn	German
Iron	VIII	Prehistoric		
Cobalt	VIII	1742	Georg Brandt	Swedish
Nickel	VIII	1751	Cronstedt	Swedish

It is perhaps of value to consider the twenty-five elements which are of direct interest in the production of steel. In the accompanying table those elements will be found scheduled. They can be divided substantially into four groups, namely, (i) the dominant alloying elements, (ii) the secondary alloying elements, (iii) appertaining and arising essentially as regards process, (iv) for protective coating.

Of these twenty-five elements, knowledge of seven—copper, zinc, carbon, tin, lead, sulphur, and last but most important of all, iron—was bequeathed to us by early civilizations, and a period of some two thousand years passed before we seriously began isolating those which are now so useful. Of the dominant alloying elements, namely, manganese, chromium, nickel, molybdenum, tungsten, cobalt and vanadium, it is of great interest to note that four of these elements were originally isolated in Scandinavia, one in France, one in Germany and one in Spain, while of the secondary alloying elements, aluminium, titanium, zirconium, niobium, selenium and copper, three were isolated in Scandinavia, one in France, and one in Britain; the last-mentioned, copper, was employed in prehistoric times.

---

* Paper read on July 25 at the Conference on Mineral Resources and the Atlantic Charter arranged by the Division for the Social and International Relations of Science of the British Association.

As regards the elements iron, carbon, and silicon, these are so fundamental as almost to escape notice, but while iron and carbon date from prehistoric times, silicon was only isolated in 1854 in France. Hydrogen, nitrogen, phosphorus, arsenic, oxygen, sulphur are to be looked upon as essentially impurities arising from process, while zinc and tin are used for coating steel in protection against rust (as of course in smaller degree are cadmium and nickel).

In an effort to be able to present a complete picture, I have sought to: (*a*) schedule the production of the relevant raw materials as regards country of origin; (*b*) schedule the countries where the raw materials were smelted or reduced to a usable form; (*c*) schedule the origin of the relevant raw materials used by the different steel-making countries. Such statistical evidence merits careful study, and although not sufficiently available for a complete statement, does point to facts of great interest.

The volume of production of an ore in a country is indicative of the achievement of economical winning but not necessarily of the resources prevailing. There may be great quantities of low-grade ore, railways may not be available and population of a suitable character may not be there. Distance, too, is determining from the economic point of view; for example, a great country may find it advantageous to obtain material from a neighbouring country rather than from within the confines of its own extended territory. The geologist locates, the mining engineer advises on practicability, and the industrialist, backed by adequate finance, seeks to develop these relevant deposits. Sound knowledge, enterprise and no little courage is demanded. The collective outcome normally is availability in reasonable relationship to world demand.

Without exception, the steel-making countries do not possess complete essential resources and must import much that is necessary. In normal times, international trade provides the necessary facilities at world prices on a reasonably economic basis. Small countries as well as large ones have successfully developed important steel industries.

To implement the foregoing it is interesting to examine a few cases and then it will be obvious, having in mind present world conditions, that it is essential to use available alloys on their intrinsic technical merits and only to the absolutely essential degree.

As regards the principal alloying elements used in the alloy steel industry, manganese ore, while widely distributed, is produced essentially in Russia, India, West and South Africa and Brazil. Nickel ore production is focused essentially on localized deposits in Canada. Chrome ore, though very widely distributed, is produced in Rhodesia and South Africa, Turkey and the U.S.S.R., and in lesser degree in Cuba, the Philippines, India, Yugoslavia and Greece. Tungsten ore is essentially produced in China, Burma and in less degree in the United States of America and South America. Molybdenum ore production is focused essentially on deposits in the United States. Vanadium ore is produced essentially in Rhodesia and South-West Africa, the United States and Peru. Cobalt ore is derived principally from the Belgian Congo, Rhodesia and Canada.

It will thus be seen that the principal steel-producing countries, the U.S.A., the U.S.S.R., Germany, Great Britain, France, Japan, Belgium, Luxembourg and Scandinavia are dependent upon the normal functioning of international trade and copious transport, particularly in the form of shipping.

Great Britain relies upon importing 30 per cent of her iron ore and the whole of her manganese, chrome, nickel, tungsten, molybdenum, vanadium and cobalt. Germany relies upon importing most of her manganese ore and the whole of her chrome, nickel, tungsten and molybdenum; she claims to recover her vanadium at home. The U.S.A. imports more than 90 per cent of her manganese ore and practically the whole of the chromium, nickel, cobalt and a substantial proportion of her requirements in tungsten. It is thus obvious that the conditions postulated in the fourth clause of the Atlantic Charter did operate even in the period between the two great wars, or how can one explain, for example, the successful iron and steel industries of Scandinavia and Belgium–Luxembourg.

One of the greatest technical achievements is the huge output of iron, and by virtue of the influence which carbon and other elements can confer readily upon it, a very wide range of properties is available. Steel may be soft and ductile, hard and of great strength, wear-resisting, rust- and acid-resisting, heat-resisting; may be of high permeability, capable of a high degree of permanent magnetism; may be non-magnetic, have a high electrical resistance, or a low coefficient of expansion. It may possess various combinations of these and other properties as required. It can be converted by added elements into any of a wide range of tool steels and steels for many special applications. These results are attained by a knowledgeable heat-treatment superposed upon a selected suitable composition.

Some fifteen elements are involved in the production of these various properties, and it will at once be apparent that millions of alloys of various compositions would need to be tested out really to put this phase of metallurgy upon a finally quantitative basis. Thus some properties may be achieved by using different proportions of different elements, and that fact, coupled with other factors operating in the world, has resulted in quite a complexity as regards the number of steels available. The obvious thing is for the producer and user in co-operation to use only those compositions which are most effective and most in sympathy with the availability of the materials.

The problems before such a collaboration are influenced by many variables. There is the peculiar combination of properties required for a particular purpose, achieved by complex compositions which, although they in practice achieve their purpose, have been found to do so by practical trial—that is, by 'trial and error' method—and it is not always easy in a steel containing a number of alloyed elements in different proportions to diagnose the extent to which amounts of each individual element contribute or to what extent the selected superposed heat-treatment is responsible for the ultimate result. Again, it can be argued that so long as the necessary mechanical and physical properties are secured, the composition and treatment are of secondary importance; this might truly be argued, were it possible by testing methods alone to ascertain completely whether the conditions for a particular service have been achieved. Laboratory tests to simulate the calls of service are valuable, but they are generally incomplete. Even the designer, try as he may, is never sure of being able to postulate completely on paper the conditions which he has to meet and then provide the means of meeting them.

Thus, by practical experimental procedure based on existing knowledge, mechanisms and apparatus are provided, built of materials which by trial are found to serve the purpose. It is, therefore, not a matter of surprise that when success has been painfully achieved by modifications here and there as dictated by circumstance, the means whereby success has been achieved are fairly rigidly adhered to. When stock is taken in a national emergency, multiplicity of types of material and of design is to be expected. The next step is to facilitate mass production by strictly limiting the number of designs and vastly reducing the number of types of material.

What has been done as regards the metallurgy of steel, particularly as regards special and alloy steels? In May 1940, the Special and Alloy Steels Committee constituted its Technical Advisory Committee with a mandate to deal with this problem. It was found that the production of the steels was governed by between two and three thousand specifications. The first step was, therefore, a meticulous study which resulted in the sorting out of the whole of the steels covered by the specifications into eighty-five categories essentially upon the basis of mechanical properties, compositions or special functions. The T.A.C. Schedule 1 to 85 did not lend itself to general publication since it was all-embracing, but it permitted the appropriate authorities and individuals to survey the interesting position thus disclosed.

The main point achieved was that it became possible to measure up needs against availability as regards the essential alloying elements. Means were found by the Steel Control, assisted by the goodwill of the industry and the consumers, to accommodate manufacture with quite reasonable success to changing conditions. Still conditions change, but in the truly indigenous British manner of adaptation to changing circumstance, the means of adaptation now exist which it may be presumed will achieve as much as is possible according to the existing conditions and needs of the moment.

The T.A.C. schedule of eighty-five categories for so many specifications was possible owing largely to the manner in which the same object was being achieved by different or slightly different compositions and treatments. Thus, as will be described, selection was possible of a relatively few appropriate compositions and treatments to facilitate mass production, but at the same time alternative steels became scheduled and so material guidance exists for change with availability as the need arises. How far can results be achieved without alloy conditions? How far can we replace nickel with chromium or chromium with nickel? How and in what circumstances are molybdenum and vanadium essential? Can we replace tungsten with molybdenum or molybdenum with tungsten? Will a modified heat treatment with a different composition give the same characteristics? A survey of the categories of the schedule assists in answering some of these questions.

In 1941 advantage was taken of the existence of the British Standards Institution to issue document *BS*970/1941, giving in the form of fifty-eight specifications the principal and most useful of the steels in the schedule covering Wrought Special and Alloy Steels for General Engineering purposes in dimensions up to 6 in. ruling section. This document was shortly followed by *BS*971, which implemented the contents of *BS*970/1941 with much technical and other useful data facilitating the successful application of the selected steels; this document sets a precedent in form. At this stage the Steel Controller issued a 'direction' through the British Standards Institution *BS*970A indicating that, in conformity with existing conditions, certain steels specified in *BS*970/1941 should in the absence of special sanctions be the steels applied in future programmes. Thus the 'En Series' of war steels entered their useful career. On March 30, 1942, a brochure was issued indexing and correlating the great mass of specifications to the steels of the Direction 970A which sought to replace them. Two remaining steps should be mentioned: *BS*970/1941 was revised and is re-issued as *BS*970/1942, and representatives of all the Services, after deliberation upon the steps already taken, issued through the British Standards Institution Document *BS*/STA5, which co-ordinates the whole of the requirements of the Services within the terms of reference with the composition and properties of the steels of the 'direction' on the basis of the En Series contained in *BS*970/1942.

This successful collective effort at unification has only been possible as a result of the firm determination of all parties to attain that which was intended. Finality in present changing circumstances is not possible, but succeeding documents under the ægis of the same authorities will, it is hoped, successfully keep up to date such essential data.

The fortunate Crusader had a superbly efficient Toledo sword of high temper; that is, the blade had a tensile strength of more than a hundred tons per square inch. This was obtained by the diffusion of carbon into wrought iron, and the steel so produced when heated above the critical point became a solid solution of carbide or carbon in iron; rapidly quenched in water from this temperature the blade was intensely hard and also brittle, but when lightly tempered by reheating to a skilfully selected temperature, material hardness was still retained but was accompanied by a remarkable toughness. Such results can only be obtained in such thin sections; if heavy pieces of such steel are quenched from the hardening temperature, the actual rate of cooling becomes so relatively slow as to allow the solid solution to break down and hardening is not achieved. Nevertheless, modern carbon steels which, different from the steel of medieval times, contain a substantial quantity of manganese, may be hardened and tempered in the form of bars of quite useful sizes with resultant considerable strength and ductility. The exploitation of such material to the greatest practical extent is most desirable at the present time.

The use of a particular composition of steel necessary for a particular application is governed by the strength and properties required and by the sectional area, or to be more correct, the 'ruling section'. If the mass is considerable and the strength required great, a rich alloy steel is essential to ensure success in hardening and therefore the possibility of superposing upon the quenched condition by tempering a desirable toughness associated with the degree of strength required.

In heavy masses where it is desired to obtain properties resulting from hardening and tempering, as much as 5–6 per cent of alloying elements is necessary, such as chromium and nickel, and these elements may be used in different proportions with a material degree of interchangeability, according to availability. Under such conditions a small proportion of molybdenum is desirable essentially to preserve higher values in resistance, when required, to the notched bar impact test and in part to reinforce the hardening properties. As the mass or section decreases, less alloy is needed, and this aspect is given quantitative guidance on alternate bases in *BS*970/1942 and *BS*971. Thus the heavy use of alloying elements should be restricted according to mass.

The remarks so far refer to the development of strength and hardness in different degree by the processes of hardening and tempering. There are a considerable number of instances where alloys used in greater quantity produce important and entirely different characteristics. 13–30 per cent of chromium and 2–20 per cent of nickel, together with lesser amounts of other elements, are necessary to produce rust-, acid- or heat-resisting steels. Large quantities of tungsten and/or molybdenum, together with material quantities of chromium, vanadium and cobalt, are used to produce high-speed cutting steels. High percentages of manganese are necessary to produce the wear-resisting properties of the austenitic manganese steel. Many other special purpose applications could be quoted. The use of such steels, owing to their high alloy content, is being carefully watched and controlled.

The problem is a considerable one: namely, how at the present time to cater for a greatly increasing demand for steels of the necessary properties, with a changing availability and a considerable deficiency in some of the essential elements. Never has a more interesting technical situation developed, for solution by scientific and technical minds.

Autocracy in science or technology is as deadly as in the political field. In these efforts within the steel industry, our work is being advanced by the friendly and enthusiastic collaboration of many minds; the co-ordination of different points of view has resulted in, and is operating, a workable procedure. Stark efficient realism is necessarily our theme.

THE TOTAL SOLAR ECLIPSE OF OCTOBER 1, 1940

THE results obtained by the joint expedition of the National Geographic Society and the National Bureau of Standards to Brazil to observe the total solar eclipse of October, 1940, are given in enviable detail in a beautifully produced monograph appearing as No. 2 in the Solar Eclipse Series of Contributed Technical Papers of the National Geographic Society. The site selected by the two organizations was at Patos, a town of 10,000 inhabitants in north-east Brazil, some 160 miles from the coast. The programme included photographing the corona in monochrome and in colour; measurements of the brightness and polarization of the corona; a spectrographic study of the flash- and coronal-spectra from 10,000 A. to 3,000 A.; measurements of sky brightness, from which the physical condition of the upper atmosphere was to be deduced; precise contact-time observations; and radio sounding of the ionosphere for the purpose of studying the effects produced by the eclipse in the upper atmosphere. Much of the apparatus taken out was specially designed for this expedition, and it must have been an anxious time when, after a clear dawn, clouds began to form at sunrise. Occasional clear patches allowed glimpses of the narrowing crescent of the sun after first contact, but during totality (8.45 a.m. local time) the sky in the neighbourhood of the sun was completely veiled, though the clouds were thin enough to allow a view of the inner corona, and an excellent flash-spectrum was obtained just after third contact. The photographic observations of the corona and the photometric measurements on the sky illumination were ruined, however, and even the radio observations, though independent of the weather, were somewhat marred by a technical mishap. However, much valuable information has been derived from those parts of the programme which could be carried through, and the monograph contains seven papers on various aspects of the results.

I. C. Gardner describes the design and construction of the eclipse apparatus, the main items of which were two corona cameras, one equipped with a rotatable polarizing screen, and two slitless concave-grating spectrographs intended to record the chromospheric and coronal spectra in the ranges 3,000–5,500 A. and 5,000–10,000 A. respectively. All the apparatus was operated by vacuum or electric lines, either automatically or by push-button control, and the exposures were made on standard aeroplane (240 mm.) roll film. Instead of using mountings which can be adjusted for future eclipses in different latitudes, cheap welded frames were made in angle-iron or steel tube, the intention being to provide the proper elevation in future by remaking the appropriate parts of the frame. Fine adjustment was provided by mounting the frames on ordinary screw jacks in concrete.

The short-wave spectrograph was operated manually when a sudden break in the clouds occurred at the end of totality, and a single first-order spectrogram 1 m. long (dispersion 2·4 A./mm.) was secured, showing the chromospheric emission lines superposed on an over-exposed Fraunhofer spectrum. Unfortunately, a mishap to a control switch on the other spectrograph prevented a simultaneous long-wave record being obtained. A contribution by C. C. Kiess gives the results obtained by measurement of the spectrogram: wave-lengths, estimated intensities and characters, origins and term combinations are listed for nearly 1,100 chromospheric lines in the region 3,227–5,398 A. The Balmer series is traced from $H\beta = H_4$ to H_{29}, but there is no sign of the ionized helium line at 4,686 A.

As in all modern astrophysical work, calibration marks were impressed on the spectrograms with the view of deriving absolute intensities for the emission lines. The intensity calibration was performed by means of a standard tungsten-ribbon lamp operated at 2,917° K. The intensity distribution in the spectrum of this lamp, as received at the focal surface of the eclipse spectrograph, was measured at 100 A. intervals between 3,450 A. and 5,350 A. by R. Stair and W. W. Coblentz, the work being described in full in one of the papers comprising the monograph. C. C. Kiess and C. J. Humphreys, in another contribution, utilize this calibration in making intensity measurements on the *b* group of Mg I in the green, on the *H* and *K* lines of Ca II in the ultra-violet, and on the Balmer lines of hydrogen. As is well known, the intensity decrement along the

Balmer series furnishes a means of discriminating between the various possible modes of excitation of the lines. From $H\gamma$ to $H\eta$ the observations agree best with the Pauli-Schrödinger formula, in which the excitation is assumed to be by direct absorption of radiation in the Lyman series; whereas from $H\theta$ to $H\varphi$, which is the limit of practicable measurements, the intensities follow closely the Menzel-Baker formula, in which the Balmer emission is assumed to be due to recombination of protons with electrons freed by photo-electric ionization of hydrogen atoms by radiation beyond the Lyman series limit.

The partial accomplishment of a very different part of the programme is described by P. A. McNally in the fifth paper of the series. The proposal here was to make accurate determinations of the times of contact by taking 260 photographs of the crescent during the partial phases. Clouds interfered with the completion of this programme, only about one half of the exposures being recorded, and only very few of these were secured within a minute of the times of contact. Nevertheless, the number of pictures taken was much greater than in any previous eclipse, and the paper shows how the observations can be satisfactorily reduced, and gives in tabular form the derived systems of corrections to ephemeris mean anomalies of the sun and moon.

The programme proposed by E. O. Hulburt was to deduce, by means of measurements of the sky brightness during the eclipse, the temperature of the upper air immediately following its illumination by full sunlight. Illuminometer measurements of the zenith sky on days previous to the eclipse had shown that the temperature during morning and evening twilight was 218° ± 15° K. for all altitudes between 20 km. and 60 km. Analysis of a few observations made during the first half of totality in an isolated patch of clear sky shows that, as was expected, the brightness at this early stage was due mainly to light scattered more than once by atmospheric particles in the umbra below 20 km. After mid-totality the clouds closed again, and made illuminometer measurements useless, since there is obviously no point in determining the brightness of the lower sides of clouds, which will doubtless be illuminated mainly by the horizon glow.

In the seventh and last paper of the monograph, T. R. Gilliland describes the radio observations, which were made for the purpose of studying the changes of ion density produced by the optical eclipse in the ionosphere. A self-contained trailer unit comprising a variable-frequency transmitter and receiver and a recording oscillograph was used at the eclipse site to record critical frequencies for the layers E, F_1 and F_2 at quarter-hour intervals on several control days before and after October 1, and at minute intervals during the eclipse. Unfortunately, a breakdown in one of the tuning condensers interrupted all recording shortly after third contact, and it was not resumed until after the eclipse ended. However, much of interest emerges from the ion densities deduced from the observed critical frequencies. In the layers E and F_1 the ionization decreased to 22 per cent of its normal value within a minute or so of second contact, whereas the F_2 ion density was still dropping at third contact and probably reached a minimum of about 50 per cent of normal about an hour after the eclipse maximum. A puzzling feature of the observations is that the recombination coefficient estimated for the E and F_1 layers depends somewhat on whether the depth of minimum or the time of minimum is considered; and a marked rise in the ion density two or three minutes before totality ended is also unexplained. The observations confirm the importance of the part played by solar disturbances in causing upper-air ionization: a distinct decrease in ion density occurred as the moon obscured a large sunspot.

Astronomers and physicists will sympathize with the members of the expedition in their bad luck with the weather, and will congratulate them on making such good use of the observational material they did manage to secure in spite of adverse circumstances.

A. HUNTER.

HENRY FAIRFIELD OSBORN AND THE AMERICAN MUSEUM OF NATURAL HISTORY

By PROF. W. K. GREGORY

ON April 8 the double event of unveiling a bust of the late Prof. Henry Fairfield Osborn and the opening of the new North American Mammal Hall took place at the American Museum of Natural History on the occasion of the annual members day. Mr. A. Perry Osborn, acting president of the Museum, presided at the meeting. In his opening address Mr. Osborn told the members of some of the effects of the War upon the Museum in the loss of men to the army and the reduced operating funds. He spoke also of the assistance the Museum had been able to give to the Government by supplying information on the geography, climate, native diseases, and so forth, of the countries to which the American armies are likely to be assigned. He then introduced to the members Dr. A. E. Parr, who succeeds Dr. Roy C. Andrews as director of the Museum.

Before the uncovering of the memorial bust, Prof. William K. Gregory made a commemorative address on "Osborn, the Scientist", of which the following is the substance:

The unveiling of the bust of Henry Fairfield Osborn and the opening of the new Hall of North American Mammals are appropriately brought together in one meeting. To Osborn's enthusiasm and unconquerable energy we owe this entire memorial building, dedicated to his friend and fellow-naturalist, Theodore Roosevelt. This building in turn forms a perfect setting for the new hall, which is filled with superb mounts of the larger North American mammals in their native haunts—beloved alike by Roosevelt and Osborn.

Osborn's scientific studies on fossil mammals began in 1877, when he and several of his classmates at Princeton, including his close friend and colleague, William Berryman Scott, made their first expedition to the Bridger Eocene basin of Wyoming. Here they discovered enough strange extinct forms of mammalian life to give them an uncontrollable urge to discover more. From this expedition sprang a long and ever-branching system of explorations, at Princeton under Scott and at the American Museum under Osborn. From the Flaming Cliffs of the Gobi Desert and the withering slopes of the Siwaliks in India, to the frozen soil of Alaska, many a "valley of dry bones" has heard the clang of the explorer's pick and yielded up its dead. Under the spell of the prophet the dry bones came together and thus it happened that in our temple of science many an ancient leviathan rears his mighty frame before us.

All this and much more was set in motion by Osborn, who often went into the field himself; but he always gave full credit to his captains and other men whom he had inspired and trained in the science of palæontology. In such a roll of honour he would undoubtedly himself inscribe the names of Matthew, Granger, Brown, Lull, Forster-Cooper, Andrews, Frick. And among the younger men of to-day are several to whom he was happy to entrust the future of palæontology.

As a student of Huxley and a disciple of Darwin, Osborn developed a broad interest in many branches of the biological sciences, as shown in his general work, "The Origin and Evolution of Life"; but his most intensive work was in the field of mammalian palæontology. His first important memoir was a systematic revision and study of the fossil teeth and jaws of the tiny mammals which were the contemporaries of the dinosaurs. Quite early (1888) began his interest in the evolution of mammalian molar teeth.

In his later years Osborn undertook to prepare a series of great monographs on the histories of the families of horses, titanotheres and proboscideans, or mastodons and elephants. In view of the heavy demands on his time from many other directions, his achievements in this field were truly enormous. Two of his great works (on the titanotheres and the proboscideans) stand out among the 940-odd entries in his bibliography and will be consulted as long as palæontology remains a living science.

Osborn's greatness as a man of science depended upon his greatness as a man. His vision, enthusiasm, conviction, persistence, persuasiveness, tolerance and restraint made him successful both as leader and investigator. Indeed, those of us who were close to him as a scientific worker immediately felt and responded to his benign influence as a man.

Dr. James R. Angell, in his personal tribute to Prof. Osborn, said that Osborn is immune to any serious peril of lack of appreciation, although only time will approximate a just evaluation of his accomplishments. His greatest contributions live on in the great institution which he served so long and so brilliantly. As himself an eminent scientific worker, constantly contributing to push forward the boundaries of knowledge, by his example inspiring the members of his staff and men of science everywhere to similar achievements, not less than by his administrative ability and his talent for interesting generous benefactors in the support of this enterprise, he left an indelible imprint upon his time. He put the American Museum of Natural History into the very forefront of the great scientific agencies of the period, stimulating throughout the nation a new understanding of the educational power of such institutions, while serving this great metropolitan community by opening ever wider to its citizens the unrivalled wealth of its superb collections. In all this undertaking he worked side by side with his loyal colleagues in the organization—*primus inter pares.*

In this process his own work came at times under severe attack, for while the well-authenticated fact is reasonably immune to assault, the inferences based upon it, the generalizations arising out of the effort to orient it amid other data and principles, unavoidably lead to corrective interpretation at other hands. The man of sincere scientific spirit is never seriously irked by this experience, provided he be not essentially misrepresented, for much of this kind of rough and tumble is inevitable in all progress. Osborn certainly had his full share of this type of conflict and would unquestionably accept with good grace such corrections and modifications of his own views as with the passing of the years the development of scientific knowledge may involve. Nor does it follow that because his own particular views may in certain cases fail to prevail, his contribution is in any way to be held lightly. Quite the contrary is the fact. Such approximation to truth as the human mind can ever attain is always the result of the clarifying increments made by successive generations of thoughtful men.

Men possessing such a combination of qualities as those of Osborn are all too rare. The good administrator is a familiar figure, the eminent man of science has many exemplars, even the man of science of deeply religious convictions, such as Osborn held, is by no means unknown; but it is extremely rare to find these gifts combined in one man, and when they are conjoined with a remarkable charm of personality and sterling integrity of character, we are confronted with one of the most unusual of the benefactions of a generous providence.

The bust of Prof. Osborn was unveiled by his daughter, Mrs. Jay Coogan. The bronze is of heroic size mounted on a rectangular plinth of polished Bois Jourdan marble. Below the name the following inscription is carved:

> "For him the dry bones came to life
> And giant forms of ages past
> Rejoined the pageant of the living."

Dr. Harold E. Anthony, head of the Department of Mammals, described the long, almost twenty-year period of planning the new Hall of North American Mammals. The new hall is much more than a collection of mammals. It is a series of vistas into the ecology of North America. It offers to the visitor a grand tour of outstanding regions of the continent. The mammals have the limelight, but the exhibits portray the geology and the botany of places which are properly the home of the animals as well as noteworthy for many other features.

The hall would attract attention if it had no mammals at all in it. It is a hall of realities, not of fancies. Each group is an actual reconstruction of a definite place, at a given date and time of day, and no detail is left to guesswork. The accessories not only look natural, they are natural. These very items were found at the place where the group was collected.

Mr. Newbold Morris, president of the Council of the City of New York, spoke of the value of the Museum in showing the earth in its past history and bringing before us again the lives of animals and peoples long gone. "If you spend enough time here you begin to place less value on your own life or the lives of those who are very close to you, because you realize you are only part of a never-ending stream. . . Every one of us is only part of a long process and here we get a feeling that perhaps human hatred and human passions are not so important. This museum, like our city, represents an ideal, something which we are always reaching for and will never attain, but we are secure in the happiness that we are still reaching for it. . . . Hatreds and passions will disappear and some day, perhaps, we will know what it is to live in a world without passion and fear."

The new Hall of North American Mammals, although far from completed, is yet an imposing example of the blending of many arts, many sciences, and the most modern methods of museum architecture, exhibition and lighting. It is 140 ft. in length by 73 ft. in width and built in the form of an 'I' with parallel aisles flanking each side of the central corridor, which extends the length of the hall. The habitat groups are recessed along the corridor and at both ends. The lighting represents the result of careful study to relieve eye-strain and to provide a restful atmosphere, with the illumination directed towards the exhibits and away from the visitor.

The backgrounds of the exhibits present a panorama of the North American continent, from Ellesmere Land, 700 miles south of the North Pole, to Mexico, and from New York State to the west coast of Alaska, with the mammals characteristic of each region. The skilled preparation of both backgrounds and specimens was the work of many artists and taxidermists under the direction of Dr. James L. Clark, head of the Museum's Department of Preparation.

The achievement of the Hall itself was due to Dr. Anthony's continuous and enthusiastic efforts, to the sympathetic understanding and aid of President F. Trubee Davison, and to the co-operation of the officials of the City of New York. The magnificent animals were collected and presented by friends of the Museum, and when all groups are installed there will be a complete series of the most characteristic mammals of the entire continent of North America. The finished groups include the Alaska brown bear, the largest carnivorous land mammal in existence, the bighorn sheep, white (mountain) sheep, Grant caribou, muskox (collected by Admiral Peary), mountain goat, Osborn caribou, Alaska moose, grizzly bear and mountain lion (puma). Nineteen groups remain to be installed, eight of these to be opened in the near future, including the bison, wapiti, Virginia deer, jaguar and various small mammals, which are also to be represented in the hall.

INTERNATIONAL TABLE OF STABLE ISOTOPES

THIS Table, together with the Fifth Report of the Committee on Atoms, was last published, in Paris, by the Union Internationale de Chimie just before the occupation of France. After that event Prof. E. Briner of Geneva very kindly offered to undertake the correspondence necessary to continue the work of the Committee. With his help I was ble, as chairman, to draw up a Sixth Report which submitted to him for publication early in 1941. Later in that year he informed me that unfortunately he had been unable to arrange for its publication, and requested me to draw up a modified report rought up to date for 1941–1942. This I did, and n February 1942 he wrote that I might soon expect he proofs of this. I have heard nothing from him nce, and as I think further delay would be unforunate, the report is appended. There has been very little published on the subject since it was drawn up and, so far as I have been able to ascertain, the other members of the Committee approve of all the lterations embodied in it.

F. W. ASTON.

Trinity College,
Cambridge.
Oct. 5.

Sixth Report of the Committee on Atoms of the International Union of Chemistry

Chairman: F. W. Aston. *Members:* N. Bohr, O. Hahn, W. D. Harkins, F. Joliot, R. S. Mulliken, M. L. Oliphant.

Owing to the impossibility of publication during 1941, this report covers double the normal period. The following changes in the Table of Isotopes are recommended:

Helium. Evidence has been obtained by means of the cyclotron that a stable isotope of mass 3 exists in Nature[1]. The abundance is very small and is estimated at about 10^{-7} per cent.

Sulphur. The parentheses indicating doubt in the existence of the very rare isotope 36 are to be removed.

Nickel. Two complete electrometric analyses have now been published, by Straus[2] and Valley[3]. Their results are given below together with those obtained in the original photometric observations[4]:

Mass numbers	58	60	61	62	64
Aston (1935)	67·5	27·0	1·7	3·8	?
Straus	62·8	29·5	1·7	4·7	1·3
Valley	67·4	26·7	1·2	3·8	0·88

Valley's work is approved by Bainbridge. His figures are in better agreement with the photometric results, and also with the chemical atomic weight, than are those of Straus. Both observers agree that 61 is 1·3 times more abundant than 64. This is in good accord with the mass spectra previously obtained by Dempster[5] and also with the original ones of Aston (re-examined) upon which the previous figures were based, but contradicts the evidence of the parabolas from which Lub[6] deduced that 61 is "with regard to 64 as 1 : 10". Valley's figures are now adopted.

Cobalt. In consequence of doubts expressed on many grounds as to the existence of a stable isotope 57, Mitchell, Brown and Fowler[7] have analysed $CoCl_2$ with a mass spectrometer. Their results show that 57 cannot be present even to 1 in 30,000 of 59. As in mass spectrometry evidence of absence is much more cogent than that of presence, cobalt is now to be regarded as a simple element.

Molybdenum. Electrometric measurements on this element have been carried out by Valley[8]. The following percentages, which he considers accurate to one per cent, are recommended:

Mass numbers	92	94	95	96	97	98	100
Abundances	14·9	9·40	16·1	16·6	9·65	24·1	9·25

They show a satisfactory small divergence from the photometric ones of Mattauch and Lichtblau, adopted in the previous report, and the original ones of Aston, and lie roughly between the two.

Rhodium. The rare isotope 101 of rhodium is subject in considerable degree to the same objections as that of cobalt above mentioned. It will therefore be regarded as doubtful, and given in parentheses, until further experimental evidence is available.

OBITUARIES

Prof. David Waterston

THE death of Prof. David Waterston on September 4 at the age of seventy-one removed one of the distinguished anatomists of the Edinburgh School and a familiar figure for the past twenty-eight years in the life of the University of St. Andrews. After graduating in arts in the University of Edinburgh he took the M.B., C.M. in 1895, the F.R.C.S. (Ed.) in 1898 and the degree of M.D. with a gold medal for his thesis in 1900.

In anatomy Waterston found his life's work and he became lecturer and chief assistant to Sir William Turner, and was one of the ablest of the many anatomists trained by that great master. In 1909 he was appointed professor of anatomy in King's College, University of London, which post he held until 1914 when he succeeded Prof. Musgrove as the second occupant of the Bute chair of anatomy in the United College of the University of St. Andrews.

He entered with zest into the life of the University, for many years was adviser of medical studies, served the University Court as a representative of the Senatus during 1929–35, and during 1930–40 was the representative of the University on the General Medical Council.

Under his direction the Department of Anatomy in St. Andrews has undergone progressive development, and he had the satisfaction of raising it to a high standard of efficiency.

A man of science, Waterston was precise in expression, critical of statements ; his powers of observation were always keen and astute, his eager mind stretching out after more and more facts. Much of his technical skill was directed to making the science of anatomy a living one, and we have testimony to this in his volume "Anatomy in the Living Model". He was joint editor of "The Edinburgh Stereoscopic Atlas of Anatomy", was one of the contributors to Cunningham's "Text-book of Anatomy" and published many papers upon anatomical, embryological and anthropological subjects. He was especially interested in prehistoric man and enriched the museum by the collection he made of his handiwork.

In addition to such specialized study he retained a keen interest in clinical medicine and found scope for his ingenious mind in the problems which presented themselves in the work of the James Mackenzie Institute. After the death of Sir James Mackenzie the Institute found in Waterston a staunch and able leader, while as one of its research workers he conducted experiments on himself in order to elucidate the mechanism of pain—a contribution of the highest value.

To those who were associated with him in his work his distinctive personality and influence were a source of continual interest, encouragement and stimulus, and to junior members of his staff he was invariably courteous and never too busy to listen to their problems and to help them by advice.

He was not only a diligent member of many of the committees which are necessary in a university, but also gave valuable service as a member of the Council of St. Leonards and St. Katherines Schools, and since 1939 he had been a member of the Town Council of St. Andrews.

He enjoyed social occasions and in the pursuit of his favourite recreation golf, he played many keen matches in the Royal and Ancient Competitions. Few knew the anatomy of the golf swing better than he did and to the end his short game lost none of its accuracy.

Many have sorrowfully paid tribute to the memory of one who will be much missed. D. R. DOW.

Prof. P. A. Hillhouse

WHEN one looks back on the career and life of Prof. Hillhouse, formerly professor of naval architecture in the University of Glasgow, who died on September 28, at the age of seventy-three, one cannot but realize that his success was due to the combination of great ability in his chosen profession of naval architecture and his personal charm.

As naval architect to the Fairfield Company he was responsible for the design of many famous vessels, but probably the Canadian Pacific *Empress* liners will be for a long time remembered as representing his most notable achievements. To appreciate fully his gifts as a designer one had to work with him. Always ready to investigate the most exacting conditions set down by the shipowners, he was never led into adopting a doubtful policy ; no one could have carried out all the preliminary design work with greater care, and one always felt that, once his decision was made, it was the best possible.

The inevitable discussions that sometimes occur between owners and builders found him quite unperturbed, and his calmness and cheerful good humour never deserted him. He was rightly considered an authority on the launching of ships, but, as in all else, he did not think himself to have better ideas than others.

On the powering of ships he had no superior, and he had a remarkable gift for making the fullest practical use of the published work of those engaged in model experiment tanks. In fact, he had no equal in mastering quickly the essential points of any available information.

As professor of naval architecture in the University of Glasgow, a position he held for twenty-one years, Prof. Hillhouse's lectures covered a very wide range. Some of his less competent students may possibly have found it difficult to keep pace with him, but his kind and understanding nature made him tolerant; and he was regarded with affection by all who passed through his classes.

Prof. Hillhouse would have made a first-class consultant, had he chosen to set up in practice. The legal cases in which he figured as technical adviser were brilliantly conducted, as he possessed the clear vision so necessary in this particular class of work

To those of us who were fortunate enough to know Prof. Hillhouse and his work, his death came as a severe blow, but no one of us can fail to have profited by knowing him and his methods.

WE regret to announce the following deaths :

Flight-Lieut. A. N. David, of the Indian Forest Service, on October 16, aged fifty-three (on active service).

Prof. Alfred Hettner, formerly professor of geography in the University of Heidelberg.

Prof. G. H. Ling, formerly professor of mathematic in the University of Saskatchewan, aged sixty-eight

Prof. K. N. Moss, O.B.E., professor of coal and metal mining in the University of Birmingham, on October 20, aged fifty-one.

NEWS and VIEWS

General Smuts and a New World Order

IT would be out of place to attempt to assess here the value of the address to members of both Houses of Parliament which was delivered on October 21 by General Smuts. Suffice it to put on record that he surveyed the war situation, paying a tribute to the people of Great Britain, but for whose exertions from 1939 onwards "this world of ours might have been lost for a thousand years, and another dark age might have settled down on the spirit of man". This survey led him to a consideration of the real nature of the present struggle as a deadly conflict for the rights and liberties of the individual and for the ideals of man's ethical and spiritual life. He concluded with some thoughts on the future and on the social and international order at which we are aiming. Our ideas on this subject at the close of the War of 1914–18 were much too vague and the concept of a League of Nations too ambitious. This time we have accepted the name of "the United Nations", which, if more moderate in outlook, seems more promising of practical effect. The Atlantic Charter also marks an important step forward in the international ordering of the world. Certain broad principles of social policy have also been agreed upon, and the Mutual Aid Agreement between the United Nations provides the beginning of international assistance of nations in need. In this field much of the work and the machinery of the League of Nations is still of value.

General Smuts summed up his view of the future in words which cannot be bettered: "We are passing beyond the ordinary politics and political shibboleths. . . . Without feeding on illusions, without nursing the impossible, there is yet much in the common life of the people which can be remedied, much unnecessary inequality and privilege to be levelled away, much commonsense opportunity to be erected as the common birthright and public atmosphere for all to enjoy as of right. Health, housing, education, decent social amenities, provision against avoidable insecurities—all these simple goods and much more can be provided for all, and thus a common higher level of life be achieved for all. As between the nations, a new spirit of human solidarity can be cultivated, and economic conditions can be built up which will trike at the root causes of war, and thus lay deeper oundations for world peace. With honesty and sincerity on our part it is possible to make basic eforms both for national and international life which will give mankind a new chance of survival and of progress. Let this programme, by no means too mbitious, be our task, and let us now already, even n the midst of war, begin to prepare for it. And may Heaven's blessing rest on our work in war and in peace."

Rutherford Memorial Lecture of the Physical Society

IT is altogether fitting that we should praise amous men, and should hold in memory those whose abours have been directed to great and unselfish nds, and who have attained results which will serve as a beacon to future ages. It is difficult for his contemporaries accurately to assess the contributions o knowledge of a lately lost leader—we stand too near his achievements to see them as clearly as we would—but there are few judgments more likely to and the test of time than that which puts the name of Rutherford alongside those of Newton and of Faraday. His insight, his simplicity and directness of mind, his almost uncanny instinct for securing the right line of advance and refusing to be diverted along side-tracks, his power of attaining epoch-making results by relatively simple means—all these are qualities which rank him with the great discoverers.

The Physical Society is to be congratulated on its decision to found a biennial Rutherford Memorial Lecture, and it is by a peculiarly happy chance that the date for the delivery of the first Lecture should fall in the year of, indeed within a few weeks of, the day of the tercentenary anniversary of Newton's birth. The Lecture will be delivered by Prof. H. R. Robinson, professor of physics in the University of London (Queen Mary College), in the lecture theatre of the Science Museum on November 6, at 4.30 p.m., and will deal with Rutherford's life and work to the end of the Manchester period. Three outstanding events in Rutherford's scientific career fall within this time—two belong to the Manchester years—and there are few better fitted, by knowledge and sympathy, to give an address which shall be worthy alike of the subject and the occasion than is Prof. Robinson.

Chemotherapy and Tuberculosis

NOT the least of the late Sir Walter Fletcher's services to medical research was his wise encouragement of research in chemotherapy. His prescience has been fully justified by the notable advances made in that subject in recent years. The conquest of a disease in former days was of epoch-making significance. The world rang with the triumphs of Ehrlich when he prepared '606'. Yet within a few years puerperal fever, gonorrhœa, cerebro-spinal fever with a mortality of 50–80 per cent, lobar pneumonia and the streptococcal infections have been shorn of their former terrors by the timely use of drugs of the sulphanilamide group. The medical profession and the general public have received these boons of the research laboratory gratefully, it is true, but with extraordinary composure, when it is remembered what a heavy toll these diseases took in the past and how many years were spent in therapeutic investigations upon them. Humanity is perhaps dazzled by the successes achieved, too dazzled to pay the due meed of recognition to the pioneers of this work.

It is possible that the long-wished-for remedy for tuberculosis may eventually come, through chemotherapy. Recently, 'Promin', the didextrose sulphonate of diaminodiphenyl sulphone, a member of the sulphonamide group, has been found by Feldman and Hinshaw at Rochester, U.S.A., to be active against the tubercle bacillus both *in vitro* and *in vivo*. Prof. W. H. Tytler, of the Welsh National School of Medicine, Cardiff, has made some experimental studies with 'Promin' (Thirtieth Annual Report for the year ended 31st March, 1942, of the King Edward VII Welsh National Memorial Association. Report of the Director of Research. Pp. 46). His results so far show that it is the most effective chemotherapeutic agent for the tuberculous guinea pig yet tested. Unfortunately, the toxicity of the drug in the high continued dosage necessary has hitherto prevented its full therapeutic application to human beings, although in local application to superficial tuberculous lesions it is efficacious. This objection may eventually be overcome, possibly by combining the administration of the drug with that of an antigenic serum or by other modifications of its toxic properties. At all events the discovery of this drug represents an important advance and may be the prelude to greater things.

War-time Lessons for Peace-time Health

THE Minister of Health, Mr. Ernest Brown, speaking at a meeting of the Cambridge University Medical Society on October 21, said that the operation of war-time services is providing a background against which the Ministry is working out ideas for future developments in public health. As regards the Emergency Hospital Service, Mr. Brown said that the old conception of independent general hospitals to serve all purposes has gradually been replaced by a more co-operative scheme in which different hospitals in an inter-dependent group have special centres for different purposes. Problems of the necessary financial arrangements, including the functions of hospital contributory schemes, of the precise place in the schemes of the local authorities, of what central control will be necessary in a hospital area including the districts of several local authorities, and similar details, remain to be worked out in detail.

Referring to the Ministry's plans to introduce mass miniature radiography to discover cases of incipient tuberculosis, Mr. Brown said that a technical committee is preparing advice for the tuberculosis authorities, to which the machines now on order will be supplied, on how the sets can be used to the best advantage. This committee is also making arrangements to train teams to work the sets and considering proposals for recording results of examinations. The procedure will be to take miniature chest radiograms of a section of the population. It is expected that about 4 in every 100 will show abnormalities on the miniature film, and a full-sized chest radiogram will be taken of these and a clinical examination made. Thus the early case is found and treatment can be begun under the best conditions for success. Though the technique of mass radiography should prove a valuable new weapon for the fight against tuberculosis, it is not a panacea; it does not supersede the established technique but rather permits its wider and more hopeful application.

Food Value of the Potato

CONTINUED success in safeguarding the essential food supply of Great Britain must largely depend on our ability to use still more home-grown foods, particularly potatoes, in place of imported energy foods. On a calorie basis, each four tons of home-grown potatoes used in Great Britain releases the shipping space otherwise occupied by a ton of wheat. Further, potatoes yield 50 per cent more calories per acre than wheat, despite the greater water content of the former crop (78 per cent against 38 per cent for bread). The components for which potatoes are nutritionally notable are iron, vitamin C and the vitamins of the B-complex. One pound of potatoes provides 330 calories, equivalent to 5 oz. of National bread or 11 per cent of the day's requirement for a moderately active man; 3 mgm. of iron, 25 per cent of the day's requirement and equivalent to that of two eggs; 100 I.U. of vitamin B_1, 20 per cent of the requirement and equivalent to that of 5 oz. of bread. One pound of freshly lifted potatoes contains 135 mgm. of vitamin C, which is almost twice the day's needs; the average C content of potatoes makes a pound equivalent to 3 oz. of orange juice. Potatoes are rich in factors of the vitamin B-complex; 1 lb. is equivalent to ½ pint of milk or 11 per cent of the day's needs of riboflavin; to 4 oz. of meat or 36 per cent of the requirement of niacin or nicotinic acid. A pound of potatoes also probably contains as much vitamin B_6 and folic acid as 1 lb. of National bread, and as much pantothenic acid as one pint of milk.

The following table shows the average composition of potatoes:

Moisture	78%		
Protein	1·2%		
Carbohydrate	16·2%		
Calories	70	per 100 gm.	
Calcium	8 mgm.	,, ,, ,,	
Iron	0·7 ,,	,, ,, ,,	
Vitamin B_1	40 I.U.	,, ,, ,,	
Vitamin C	9 mgm.	,, ,, ,,	
freshly lifted	30 ,,	,, ,, ,,	
before Xmas	12 ,,	,, ,, ,,	
after Xmas	6 ,,	,, ,, ,,	
Riboflavin	0·07 ,,	,, ,, ,,	
Nicotinic acid	1·4 ,,	,, ,, ,,	
Vitamin B_6	0·15 ,,	,, ,, ,,	tentative values
Pantothenic acid	0·3 ,,	,, ,, ,,	
Folic acid	0·12 ,,	,, ,, ,,	

At the present time the amount of potatoes purchased per head per day is less than 1 lb. This represents less than 13 oz. of edible potato. In Germany and in Ireland, more than 2 lb. a day are eaten as a national average.

Farming in Great Britain

"WAR Farming and After" was the title chosen by Lord Cornwallis for a paper to the Farmers' Club at the centenary meeting held in London on October 6. Using the first-hand knowledge gained as chairman of the Kent Agricultural Executive Committee, Lord Cornwallis outlined the problem facing British farming at the outbreak of war and showed how an ill-prepared and impoverished agriculture has risen to the occasion and achieved the remarkable result of 5 million acres gained for the plough in three years. Not only has this area been converted from grass or waste into arable, but also the standard of farming has been improved, and "the lovely land of England is beginning to look as if someone cared for it". The gain of human food has not been secured at the cost of the vitally important milk supply, for the dairy herds have been maintained in a remarkable manner largely on home-grown foods. The organization that has brought this about—the county executive committees, their technical advisers, and all who worked on the land—has done a great service to Great Britain, and there is every indication that progress will continue. With farming on its feet and pulling its weight, all connected with the land have their minds fixed on the future of the industry after the present emergency has passed. The Government is pledged to maintain the stability of home farming until a permanent post-war policy can be put in action. This, as Lord Cornwallis said, implies a measure of control and the insistence on a certain standard of efficiency.

Earthquakes in Guatemala

THE United States Coast and Geodetic Survey in co-operation with Science Service and the Jesui Seismological Association, on a basis of instrumental reports from 23 seismographic observatories, ha determined the epicentres of recent earthquakes in Central America. The first was on August 6, 1942 at 23h. 37m. U.T., and the second on August 8, 1942 Both had epicentres near latitude 14·4° N., longitude 90·9° W., which is to the south-west of Antigua

The first earthquake had a depth probably greater than normal, and the second was an aftershock of the first. Both shocks happened in an acknowledged seismic zone.

Exhibitions of Photography in Science and Industry

THE Association of Scientific Workers is arranging an exhibition, "Photography in Science and Industry", to be held during November in the rooms of the Royal Photographic Society at 16 Princes Gate, London, S.W.7. The exhibition will be opened by Sir Robert Watson Watt, president of the Association, under the chairmanship of Mr. D. McMaster, president of the Royal Photographic Society, on October 31 at 3 p.m. The field covered by the exhibits will be wide and have particular reference to the war effort, including work on machine movement analysis, radiography of castings, etc., mapping and surveying, mass examination for tuberculosis, crystallography, astronomy, nuclear physics, template making, etc. Exhibitors include the Ministry of Information, technical branches of the three Services, individual technicians and the large photographic firms. During the last decade a number of specialized photographic techniques of application to industrial problems have been developed, but although the results, published in technical journals, have become familiar to many workers, the number of people employing photography as an industrial tool is still small. It is hoped that the Exhibition will do much to familiarize engineers, scientific workers, medical men and others with the methods used by specialists, and suggest their use as a direct contribution to the war effort in fields other than those illustrated. During the course of the exhibition, lectures will be given on various applications of photography; the Royal Photographic Society is arranging a symposium on industrial radiography to be held on November 21 at 2.30 p.m., and the Society's Hurter and Driffield Memorial Lecture will be delivered by Dr. S. O. Rawling on "Sensitometry since Hurter and Driffield", on November 28 at 3 p.m.

An exhibition of photographs and apparatus showing "Photography's Part in the War" will be opened by the Right Hon. Lord Brabazon of Tara, at Kodak House, Kingsway, W.C.2, on November 3. The exhibition will be open to the public at 2 p.m. on that day, and on weekdays 9.30–5.30, Saturdays 9.30–12.30, for three weeks. Admission is free. Among the subjects illustrated are aerial reconnaissance, applications of photomicrography, high-speed photography, slow-motion cinematography, industrial radiography, photo-elastic analysis, mass radiography against tuberculosis, and the production of Airgraph letters.

Exhibition of Soviet Life in War and Peace

SOVIET medicine and health services will be strongly featured in the National Exhibition of Soviet Life in War and Peace which will be held at the Wallace Collection, Hertford House, London, W.1, during November 8–22. Ten national organizations, in addition to the Ministry of Information, have co-operated in the production of the Exhibition, which will be opened by M. Maisky, the Soviet Ambassador, and Sir Edwin Lutyens, the president of the Royal Academy. It is designed to give a comprehensive picture of the life of the Soviet people from 1917 onwards. The great achievements which have been made will be recorded, and there will be displays of Soviet costumes, books, pottery, etc. In dramatic contrast to the sections devoted to peace-time developments will be those illustrating the epic feats and tremendous sacrifices made by our Russians. There will be daily film shows, music recitals and lectures. Among those contributing to the programmes are Prof. A. V. Hill, Dr. Joan McMichael, Dr. Walton, Profs. H. Levy and C. H. Reilly. Full details can be obtained from the Secretary, 150 Premier House, Southampton Row, W.C.1.

Chemical Society Research Fund

HITHERTO, the Research Fund Committee of the Chemical Society has met in December of each year to consider applications for grants from the Research Fund. In view of present conditions, however, the Council has decided that for the present, applications for grants shall be considered as and when received. Forms of application for grants are obtainable from the General Secretary. All those who have received grants, accounts of which have not been closed, are reminded that reports should be sent to the General Secretary not later than Monday, November 16.

The Night Sky in November

NEW moon occurs on November 8d. 15h. 19m. U.T., and full moon on November 22d. 20h. 24m. Conjunctions during the month are as follows: Nov. 7d. 13h., Mercury in conjunction with the moon, Mercury 3° S.; Nov. 10d. 10h., Mercury in conjunction with Mars, Mercury 1·1° N.; Nov. 23d. 15h., Saturn in conjunction with the moon, Saturn 3° N.; Nov. 27d. 12h., Jupiter in conjunction with the moon, Jupiter 3° N. Occultations of stars brighter than mag. 6 are given below:

	d.	h.	m.	
Nov.	14	20	38·1	29 Capricorni
„	16	21	19·7	83 Aquarii *m*
„	17	22	59·2	27 Piscium
„	18	00	36·2	29 Piscium
„	20	01	30·5	ν Piscium

Mercury can be observed in the morning at the beginning of the month. Venus and Mars are too near the sun to be favourably observed. Jupiter can be observed soon after 10 p.m. and Saturn shortly after sunset. The Leonid meteor shower is due on Nov. 13–14, the radiant point being at R.A. 10h., Dec. +22°, and the Andromedes on Nov. 18–24; the radiant is near R.A. 1h. 40m., Dec. +43° about the middle of this period, west of γ Andromedæ, but neither of these showers which were once quite conspicuous displays has shown much activity in recent years.

Royal Society of Edinburgh: New Officers

AT the annual meeting of the Royal Society of Edinburgh held on October 26, the following officers were elected: *President*: Prof. E. T. Whittaker; *General Secretary*: Prof. James P. Kendall; *Secretaries to Ordinary Meetings*: Prof. R. J. D. Graham and Prof. W. M. H. Greaves; *Treasurer*: Sir Ernest Maclagan Wedderburn; *Curator of Library and Museum*: Dr. John E. Mackenzie; *Councillors*: Prof. Edward Hindle, Prof. J. R. Matthews, Sir Arthur Olver, Dr. David Russell, Dr. Robert Campbell, the Right Hon. Lord Cooper, Prof. E. W. H. Cruickshank, Sir J. Donald Pollock, Mr. Stanley Cursiter, Dr. Douglas Guthrie, Prof. J. W. Heslop Harrison, Mr. Andrew W. Young.

LETTERS TO THE EDITORS

Frictional Properties of Bearing Metals

MOST bearing alloys consist of a matrix of a soft metal in which are distributed uniformly small crystals of a harder metal. Such a structure has been found by long experience to possess the most satisfactory mechanical, frictional, and low-wearing properties. It is usually supposed that the hard constituent carries the load, while the soft matrix serves to distribute the pressure uniformly and to embed abrasive particles in the lubricant[1]. The hard phase also stands out in relief from the soft phase at room temperature, and such a surface of minute hills and valleys is often said to possess desirable lubricating qualities. On account of the higher thermal expansion of the softer constituent, Kyropoulos[2] states that the latter is able to take the load at higher temperatures, that is, under running conditions. On the other hand, the opinion has been expressed[3] that a single soft metal constitutes as efficient a bearing as the conventional structure of hard crystals in a soft matrix. In actual practice, of course, a variety of different bearing alloys are used depending on the conditions of sliding. When the conditions are severe, as at high speeds and high and varying loads, only certain types of alloy structure can be used with success, and the homogeneous metal is unsatisfactory. It does therefore appear that a heterogeneous structure possesses definite advantages for bearing metals.

Some recent frictional studies have brought to light the interesting result that a thin film of a soft metal on a backing of a harder metal gives a lower friction against a steel slider than for the two types of metal separately. The friction was measured on the Bowden-Leben apparatus[4] in which the frictional drag on a small slider, held and restrained by a bifilar suspension of high frequency, is measured while a flat lower surface is moved under it. Such an arrangement (described more fully in the original reference) enabled the rapid fluctuations in the friction during slow sliding to be followed in detail. Table 1 gives the results for a small hemispherical slider of steel, 2 mm. in diameter, sliding on a lower plate of copper before and after a thin film of a soft metal had been wiped out on it by hand. The friction on the soft metal alone is given for comparison.

TABLE 1.

Upper slider: steel hemisphere, 2 mm. in diameter. Load, 400 gm. Speed of sliding, 0·003 to 0·006 cm./sec.

Lower surface	Average coefficient of friction at room temperature (20° C.)
Copper	0·3 to 0·7
Lead	0·4 ± 0·1
Film of lead wiped on to the copper surface	0·03 to 0·08
Cadmium	0·3 ± 0·1
Film of cadmium wiped on to the copper surface	0·09 ± 0·005
Tin	0·5 ± 0·1
Film of tin wiped on to the copper surface	0·15 ± 0·01

The values were usually the same at 100° C., with the exception of the layer of tin on copper, which broke through quite readily with a corresponding increase in the friction. On other metals the results were essentially similar, but if the hardness of the metal backing became too great, the film of soft metal was easily penetrated and the friction rose to the value obtained on the hard metal. The lubricating action of the soft metal would appear to be analogous to that of a viscous grease in a bearing or mud on the road. That is, a small area of contact is achieved on the hard metal substrate, while the soft metal at the area of contact causes the adhesion and deformation resistance to be low, and, in fact, acts as a viscous fluid lubricant. It will be noted that the coefficient of friction may become considerably lower than that observed for a well-established boundary lubricant such as oleic acid, where $\mu = 0{\cdot}11$ for such surfaces.

The influence of the thickness of the film of soft metal on the value of the coefficient of friction has not yet been investigated in detail. The results obtained so far show quite clearly that the value of μ for thick films of lead on copper approaches the lead value, while very thin layers become easily penetrated to give the friction of the hard metal. There is thus a minimum friction observed for a certain thickness of the softer metal layer, which in the case of lead on copper at temperatures around 100° C. may become as low as $\mu = 0{\cdot}025$. The values mentioned in Table 1 for lead, cadmium and tin were obtained for thicknesses of the soft metal produced by simply rubbing it over the copper surface a few times. In general, it was always found that the coefficients of friction were in the order, lead < cadmium < tin, for such layers of these metals. It is clear, however, that differences in the lubricating efficiency for a particular film would depend on a number of factors, among which may be mentioned the film hardness, shear strength, degree of hardening, and self-annealing and the presence of non-metallic molecular layers on the surface.

Additions of a boundary lubricant reduced slightly the already low values of the friction of these thin films. Corrosive lubricants, such as oleic acid or an oxidized oil, actually increased the friction after a short time due to the removal of the film of soft metal by chemical attack. Although these experiments described have all been carried out at slow speeds of sliding, a few experiments have shown that thin layers of lead on copper can function as lubricants at speeds approaching those in an actual bearing.

These results suggest that in a heterogeneous bearing metal the soft phase wipes out over the hard phase during sliding. Under severe conditions in the bearing, when both the fluid and the boundary lubricant films break down, this thin layer of metal may function as a lubricant for a brief interval until normal lubricating conditions are re-established. Experiments with a lead-copper alloy have supported this hypothesis. Table 2 shows the results obtained for an ordinary lead-copper alloy containing 24 per cent lead.

TABLE 2.

Upper slider, load, and speed as before.

Lower surface	Average coefficient of friction	Temperature
Lead-copper alloy (24% Pb)	0·3 ± 0·05	20° C.
Lead-copper alloy after 50 slides in the same track	0·08 ± 0·01	100°
The same track cooled down to room temperature	0·08 ± 0·01	20°

Similar results have been obtained with other bearing metals with the same type of structure.

A comparison of Tables 1 and 2 shows fairly clearly that, although at room temperature no amount of lead detectable by its lubricating action comes out of the alloy, at 100° C. lead is wiped out and considerably reduces the friction to the same order of magnitude as for a film of lead rubbed on to the copper by hand. Since the superior bearing qualities of lead-copper alloys become evident at high loads, speeds and temperatures, it seems probable that their good anti-seizure properties are the result of lubrication by a thin lead film when metal to metal contact occurs under conditions of lubrication breakdown. It is thus important that the structure of the alloy should be such that the lead can flow to the surface from underneath, and that it should not be distributed as isolated aggregates. The importance of the availability of lead in lead-bronze bearing alloys has been emphasized by Wood and Harrison[5], and our experimental results confirm their expressed opinion on the type of structure to be aimed at in a high-duty bearing metal.

The above is a record of work carried out for the Department of Scientific and Industrial Research; it was submitted to the Department on September 3, 1940, but, at that date, publication seemed undesirable. Copies were sent, however, to interested parties at that time.

Electrical Properties of Polystyrene

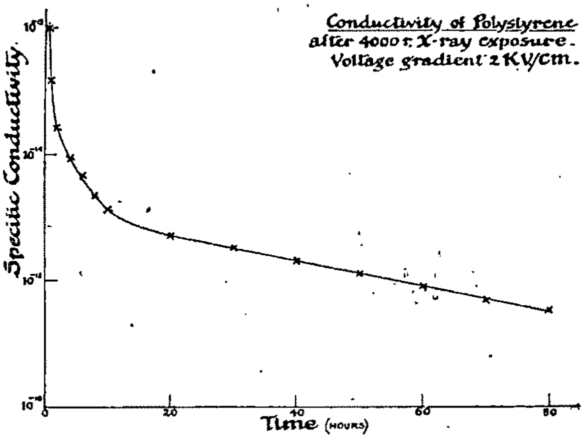
THE value of polystyrene and of certain other organic plastics as dielectrics for high-frequency apparatus is well known. The power factor for polystyrene at frequencies of 10^6–10^7 c./s. is of the order of 0·0002, a figure much lower than that for most insulators.

Other properties of this material render it very suitable for insulating purposes, notably its low water absorption, and resistance to cracking.

We have recently investigated the direct current conductivity of this same substance with a view to its use in instruments for radiological work. A cylindrical condenser was used for this purpose, with a closely fitting cap to exclude air ionized by cosmic rays, and the charge was observed by an electrometer after standing for a period of the order of 1–2 weeks. Great care was taken to keep the surface of the insulator clean and dry.

The result found for an average sample of polystyrene was a specific resistance of 3×10^{20}. Surface leakage could not be eliminated completely, and this figure is, therefore, a lower limit. It is, however, some 1,000–10,000 times the values that have been published from time to time, and greatly in excess of the value for ordinary insulators, such as glass, ebonite, etc.

When X-rays are passed through the substance its resistance falls; the amount of fall depends on the intensity and the duration of the radiation, but may be by a factor of 10^8 or more. Moreover, it has been found that the conductivity so induced lingers for a very considerable time after the X-rays have been cut off. The accompanying curve shows the effect during a period of 80 hours following a brief exposure. At the end of this time the material is still far from back to its original state.



These qualities of a material now used widely for electrical work are likely to become of increasing importance. It is the purpose of this note simply to record the results, but it is clear that they are of decided physical significance, and their full interpretation in terms of the structure of the material is likely to be of great interest.

I am indebted to Dr. J. E. Roberts for introducing this valuable material to radiological work.

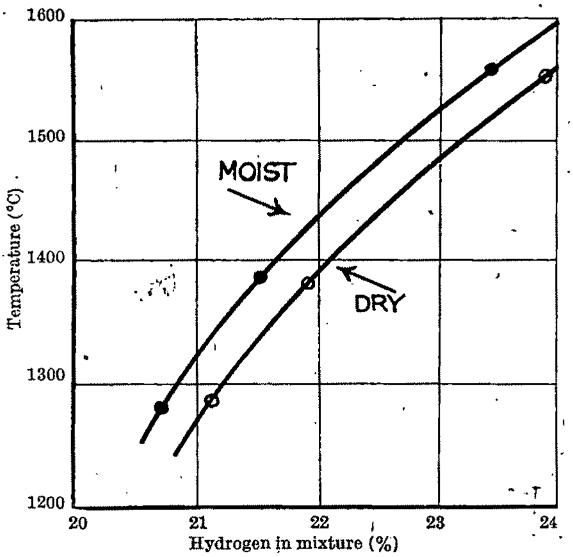
Influence of Water Vapour on Flame Gas Temperatures

THE influence of water vapour upon the combustion of carbon monoxide is well known, but its influence upon the combustion of hydrogen is not so well known.

It has been shown that flame gases resulting from closed-vessel explosions of moist mixtures of hydrogen and air contain less latent energy than those resulting from explosions of dry mixtures[1]. We have just completed a series of temperature measurements in the flame gases from moist and dry hydrogen - air mixtures which show that this is so also in the case of open flames. These measurements, which were recorded by means of thin quartz-covered platinum wires, are shown in the accompanying figure. It will be seen that for any given hydrogen content the moist flame gas temperature is 40–50° C. higher than the dry flame gas temperature, and this in spite of the fact that the calculated temperature for the moist mixture is about 15° C. lower than that for the dry mixture.

David and Pugh previously reported that the temperature attained by an uncoated platinum-rhodium wire immersed in carbon monoxide flame gases was higher when the mixtures were moist than when dry[2]. As it is now known that an abnormal amount of dissociation obtains in flame gases and that the dissociated gases combine on a platinum



surface[3], it was thought desirable to repeat these experiments using quartz-covered wires. The results, however, were very similar in that they showed similar temperature differences for moist and dry mixtures.

It will be remembered that, in the determining of flame-gas temperatures by the sodium line reversal method, water vapour is usually introduced into the inflammable mixture along with the sodium salt. For this and other reasons[4] we regard the sodium method as unreliable.

Intravenous Glucose Tolerance Curve

In the usual intravenous glucose tolerance test, the blood-sugar is measured at intervals after a single rapid (2–3 min.) injection of glucose, and plotted against the time, as in the accompanying diagram. The resulting curve has hitherto been called hyperbolic, parabolic, and so on; but on plotting the data of some 35 tests on psychotic patients (performed in collaboration with Dr. D. Russell Davis, to whom grateful acknowledgement is made), I find that the points are closely fitted over all, or nearly all, the time period 5–90 min. by an exponential curve of the form

$$y = y_0 + Be^{-kt}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where y is the blood-sugar, t the time measured from the mid-time of the injection, and y_0, B and k are constant for any particular test. Equation 1 applies also to numerous tests taken from the literature[1]. For example, the diagram is based on a test by Jörgensen[1]; the circles represent the experimental values, while the solid curve represents equation 1 with the following values for the constants: $y_0 = 30$ and $B = 300$ (mgm. per 100 ml.), $k = 0{\cdot}0214$ (min.$^{-1}$). The fit of the curve is even better in many of our own tests, but none extended beyond 90 minutes.

During the first 5 minutes or so, y falls much more quickly than equation 1 allows (y was greater than 385 at $1\frac{1}{2}$ min. in the test illustrated). Immediately after the injection, glucose diffuses rapidly out of the blood-stream[2]; and it is now suggested that when equation 1 begins to apply, the glucose concentrations in plasma and extravascular fluid have become roughly equalized. If this be so, and the glucose distribute itself evenly through a volume V_G of body fluid, then as a rough estimate

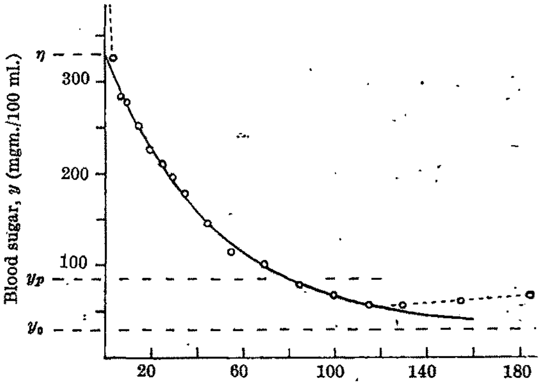
$$V_G = G/(\eta - y_p), \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where G is the amount of glucose injected, y_p is the pre-injection blood-sugar, and η the value of y given by equation 1 when $t = 0$ (see diagram). I have calculated V_G for a number of tests, and found it to be correlated with the surface area (A) and the body-weight (W) of the subjects. Mean values of V_G/A and V_G/W are given below for three groups of subjects: I, psychotic; II, normal (? children—tests by Crawford[1]); III, normal adult (tests by Lozner *et al.*[1]).

	No. of subjects	Mean V_G/A (l./m.^{2})	Mean V_G/W (ml./100 gm.)
I	12	7·15	21·3
II	9	—	19·4
III	15	6·94	19·3
		Mean V_T/A	Mean V_T/W
IV	31	7·15	18·8

For comparison, row IV shows the result of some recent determinations[3] of the thiocyanate distribution volume as calculated by the uncorrected formula[4] (V_T). This is believed roughly to represent the extracellular fluid[4,5] together with red cell water. The table suggests that V_G is of the same order as V_T, namely, about 20 ml. for each 100 gm. of body weight, not 70 ml. as for the total body water. This is consistent with the hypothesis that, after intravenous injection, glucose diffuses rapidly into the extracellular fluid and red cells. That there should be a low or negligible concentration inside the tissue cells is reasonable: at least, this contention is supported by sugar analyses in the muscle of the cat[6] and rat[7]. Also, from infusion experiments on the eviscerated cat, Burn and Dale[8] concluded that glucose spreads through about 17 ml. of fluid per 100 gm body-weight.

If it can now be assumed that when equation 1 is obeyed, plasma- and extracellular fluid-glucose are in equilibrium, then the rate of fall of blood-sugar ($-dy/dt$) will be proportional to the rate of remova



Intravenous glucose tolerance test (20 gm. glucose). Circles: experimental values (data of Jörgensen [1]). Solid curve: $y = 30 + 300\,e^{-0{\cdot}0214t}$

of glucose by the tissues. The latter will then bear a linear relationship to the blood-sugar, since, on differentiating (1),

$$-dy/dt = ky - ky_0. \quad . \quad . \quad . \quad . \quad . \quad (3)$$

This interpretation of equation 1 is in accord with the finding that the rate of utilization of glucose by extrahepatic tissue of the cat increases linearly with the blood-sugar[9]. Indeed, if the penetration of glucose into the cell involves an "active process"[6] which limits the rate of utilization, equation 3 might be a reflexion of the kinetics of this process.

It is remarkable that the many influences, including an increased insulin secretion[10], to which the blood-sugar is subject, should not distort the curve. Equation 1 is even obeyed during part of the 'hypoglycæmic phase' (see diagram). In the end, however, the regulating mechanisms[10] come into play, and the blood-sugar begins to rise.

This work is being continued, and I hope to report it in detail elsewhere.

Vitamin C from Green Tomatoes

Loss of vitamin C by mincing a natural product and thus setting free ascorbic acid oxidase has been shown to occur in orange peel (Lampitt and Baker[1]), and in cabbage and swedes (Pyke[2]; Lampitt, Baker and Parkinson[3]). Experiments in this laboratory have shown that the destruction of the vitamin is especially rapid in green plant tissue (for example, 80 per cent loss in 1 minute in shredded lettuce). We, therefore, thought it of interest to compare the rate of loss of the vitamin in green and in red omatoes.

The results summarized in the accompanying table how that when tomatoes are pulped, as would occur in mincing for the preparation of chutney, 92 per ent of the vitamin may be destroyed in 7 minutes in green tomatoes, whereas in ripe red tomatoes only 27 per cent is lost. Pyke's results on the importance of avoiding too fine a state of subdivision of reen vegetables have been confirmed. Unripe tomatoes chopped into medium-sized pieces lost nly 18 per cent on standing overnight, while similar tomatoes coarsely sliced lost only 11 per cent in the same period. Pulped green tomatoes put immeiately into vinegar diluted 1 in 10 with water lost 80 per cent on standing overnight. The pH of the pulp in the diluted vinegar determined on the glass electrode was 3·7. The pH of ripe tomato juice is usually below 4·5 and that of the flesh is below 5. In unripe tomatoes the pH of the juice and flesh may be much less acid or even slightly alkaline. The pH of the skin appears to remain alkaline throughout ripening. The oxidizing enzymes which are probably responsible for the destruction of the vitamin are concentrated in the skin and flesh and practically absent from the juice.

EFFECT OF DIFFERENT TREATMENTS USED IN PREPARATION OF CHUTNEY ON VITAMIN C CONTENT OF UNRIPE AND RIPE TOMATOES.

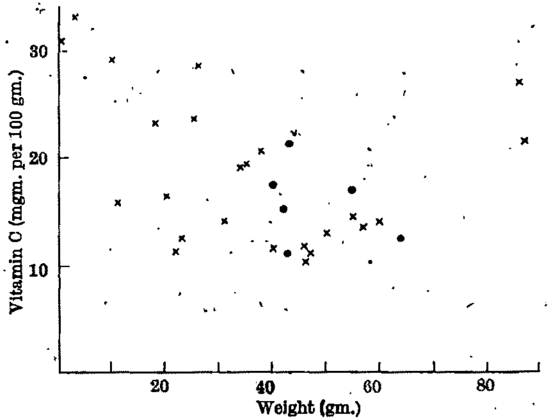
Results quoted as percentage of initial value, as determined in replicate portions of same tomatoes by 2:6 dichloroindophenol titration.

Result marked * obtained on pulped tomato added within 1 minute of pulping to vinegar diluted 1 in 10. Allowance has been made for the loss (about 11 per cent) of vitamin C during the minute required for pulping.

The table is compiled from results obtained on a number of different tomatoes tested at different times. In two instances two different tomatoes were tested for the same period of time, the results being given separately (thus, 72 and 74).

Experiments are being carried out on the effect of ripening on the vitamin C content of tomatoes. So far, the results indicate that the vitamin C content does not increase appreciably during ripening. Data on a number of tomatoes given in the accompanying graph show no significant difference between the average vitamin C content of ripe tomatoes (indicated by dots) and unripe tomatoes (indicated by crosses). Moreover, small tomatoes contain at least as high a concentration of vitamin C as large tomatoes. This applies even to tiny fruit weighing less than 1 gm. Experiments are also in progress on the effect of high concentrations of sugar such as are used in making chutney. Preliminary results indicate that these do improve the stability of the vitamin.

The conclusions we draw from these results (which are to be reported in detail later) are that, to avoid



Vitamin C content of tomatoes

loss of vitamin C: (1) no tomatoes should be discarded merely because they are small or unripe; (2) unripe tomatoes when being made into chutney should not be cut too finely, and should be put immediately into strong vinegar to which sugar should be added without undue delay.

Estimation of Moisture in Living Tissue

IN view of the statements made in recent letters[1] in NATURE regarding the estimation of moisture by distillation with an immiscible liquid, and the relationship of such figures to those obtained by oven drying, the results we have obtained recently may be of interest.

Comparison has been made of the apparent 'moisture content' of dehydrated vegetables by several methods: (*a*) distillation with toluene (Dean and Stark[2]), (*b*) vacuum oven at 70° C. and less than 50 mm. pressure, (*c*) hot-air oven at 115° C., and (*d*) steam oven at 96° C.

The results will be reported in full elsewhere, but in general they bear so little resemblance to each other as to give serious cause to doubt whether the figure for 'moisture' returned in many analyses has any significance unless the method is specified. The Dean and Stark method gave results higher than the vacuum oven, but lower than the hot-air oven, and for carrots, onions and cabbages it gave no indication of reaching a constant figure even after thirteen hours distillation. Potatoes and parsnips, on the other hand, gave a constant figure fairly quickly. The loss of weight in the vacuum oven became constant in about 5–8 hours for all vegetables, the other ovens requiring 8–16 hours for onions, parsnips and potatoes, but showing little approach to constancy with carrots and cabbage. This latter effect appears to be due to changes in the structure of the plant materials during the heating, for they change considerably in colour in both the hot-air and steam ovens, although not in the vacuum oven. The standard error of the mean was lowest in the vacuum oven, higher in the steam oven, and much higher in the hot-air oven.

As examples of the variations found the following figures may be quoted.

	'Moisture' by			
	Hot-air oven (115°)	Steam oven (96°)	Vacuum oven (70°)	Toluene distillation
Carrots	15·08	8·52	5·45	11·2
Cabbage	16·05	12·04	5·44	11·1
Potato (v. Factor)	11·98	10·37	10·50	11·5

Anemotaxis in Soft-skinned Animals

LITTLE is known about the effect of wind on the orientation of animals on the ground. Some insects resting in exposed places will often head upwind[1]. The newt *Triton tæniatus* walks in the same direction as an artificial air current[2]. Riders and airmen are familiar with the fact that horses tend to stand with their backs to a strong wind.

Experimenting with slugs (*Agriolimax reticulatus, Arion subfuscus* and *hortensis*) on a turning table, it was observed that after several minutes turning they would always bend their heads against the direction of the passive rotation, regardless of whether they were originally facing towards the centre or the periphery. It was assumed that this reaction was caused by the air moving over one side of the body. Animals were then exposed on a stationary table to artificial air currents coming from a tube. (1) If the current was so gentle as to be scarcely perceptible on the observer's cheeks, the tentacles of the animals, after an initial retraction, expanded towards the source of the current, the animal frequently raising its head from the table and testing the current with all four tentacles. (2) However, a strong air current coming from one side, best directed a little from above and behind, led to the contraction of the nearer tentacle or even the whole head, and to a subsequent sharp turning of the animal to face down wind. The most likely mechanism for both reactions depends on the wind bending the animal, and its tentacles in particular[1]. According to the intensity of the wind, propioreception of the bending force may then induce the positive or the negative reaction. This assumption is supported by the observation that a much stronger wind is needed to cause the bulky *Limax maximus* to turn away than is required for the smaller species.

Similar reactions as in the slugs may be observed in *Helix hortensis* and *aspersa,* earthworms and maggots (of Calliphora, Drosophila).

The positive anemotaxis described may be important for the animal's olfactory orientation. The negative reaction may reduce the rate of desiccation or lead the animal to shelter.

The Public Schools in Great Britain

I SHOULD like to make a few comments upon th recent communication by the number of distinguishe men of science discussing the Public Schools in Grea Britain[1].

I do not know how much first-hand and up-to-dat knowledge the signatories have of the working of th Public Schools; in the course of the communication the lay down a number of general propositions without pro ducing evidence in support of them—for example that men brought up in the Public School traditio are "out of touch with modern social realities", an that the teaching of science under the condition existing in these Schools "tends to become an esoteri cult, isolated from social purpose". Those who hav had long experience of teaching in Public School either boarding or day or both, will not, I think, find reason to agree with either of those very broad and unsupported statements? In one other matter too the signatories are definitely misinformed; that is, where they say that the proposed offer of places in the Public Schools to boys previously trained in public elementary schools has been imposed upon the Public Schools by their financial necessities. How they can venture upon this statement without knowledge of the finances of the Schools is not clear. I would simply say two things—first that a large number of the Public Schools are in a flourishing state, and have no need to make up their numbers in that or any other way; and secondly, that anyone who is acquainted with a school balance-sheet knows well that the admission of a proportion of boys with public assistance would not save the finances of any school, if they were in at all a serious condition.

I suggest that no good purpose is served by general assaults of this kind; they are mere blows in the air. The Public Schools have as many strong points and as many weak points as any other educational institution of human contriving; but the headmasters believe that the Schools have something of value to offer to the nation, and they are anxious that this offer should be made available to all British parents who desire to make use of it for their boys, irrespective of their means. We believe that we can render this wider service best if we are allowed to retain our spiritual and educational independence. If any or all of the signatories would like to meet the Committee of the Headmasters' Conference for a further discussion of these or any other questions that may arise out of their manifesto, we should be delighted to make arrangements for that purpose. Much unnecessary misunderstanding might be avoided and real progress towards the common object might be achieved, if groundless general charges could be abandoned and an effort made to grasp the problem on the basis of facts as they are, and not vague suppositions.

Spencer Leeson.

Role of Protozoa in the Activated Sludge Process

The importance of Protozoa in determining the condition of the sludge has been reported by a number of workers and, more recently, the special significance of Vorticella has been emphasized by Pillai[1, 2] and Reynoldson[3]. Further detailed study has revealed the special role of the genus Epistylis, of which not less than six species have been found to be actively associated with the installations in India. These forms flourish in the aeration chambers, forming fluffy masses attached to the sides of the aeration tanks.

During aeration, the Epistylis, which number at least 16,000 per ml., get largely dispersed and thus come into direct contact with the colloids of the sewage which they collect and carry down in the form of flocs. Experiments with isolated forms have shown that, in this action, the Epistylis are at least twice as efficient as the Vorticella and many times more so than all the other forms put together.

The exact mechanism of flocculation is still somewhat obscure. The Protozoa carry a negative charge which is of the same sign as that of the colloids of sewage; they do not secrete any enzyme possessing any marked clotting action excepting on milk. They have, nevertheless, a direct action on sewage colloids in a manner resembling, but more efficient than, that of chemical flocculents.

Parallel studies with activated sludge as well as the equivalent suspension of mixed Epistylis (with the associated bacteria) have shown that the latter accounts for more than 70 per cent of the reduction in 4 hr. oxygen absorption, albuminoid and ammonia nitrogen observed in the former. About 80 per cent of the total nitrification also takes place in presence of Epistylis. Besides concentrating nitrogen in the sludge, the Epistylis cells themselves are quite rich in nitrogen, containing more than 8 per cent dry weight.

Other observations may be summarized as follows:

Prolonged aeration, especially without any inflow of raw sewage, leads to the steady disruption of the protozoan cells and even their ultimate disappearance. This condition, which is associated with the black or 'burnt out' sludge, shows that steady inflow of raw sewage is necessary for the development and active functioning of Protozoa.

With reduced air supply, the protozoan cells tend to diminish in numbers. The little sludge that is left is not reactive and does not settle readily. It gets filled with gases formed by bacterial action and eventually floats up. The phenomenon of 'bulking' which is often noticed under such conditions can thus be explained.

The reversion of the sludge observed either on prolonged standing or during sludge digestion is a drastic form of the above phenomenon, the protozoan cells first floating up, then getting disrupted and finally digested by the bacteria.

Even under conditions of adequate aeration, the presence of certain other forms of life interferes with functioning of the Protozoa and hence the purification. An outstanding example of this is the invasion of the Chironomus larvæ[4], which, under certain conditions, enter the tank in large numbers. These attack the Protozoa, especially those of the Epistylis sp., using the slimy colonies for the formation of their characteristic protective tubes and for their food. As the result of this, the functioning of the process is completely paralysed; and until the larvæ are completely destroyed and the plant re-started, there is no purification to be seen.

Some preliminary studies on the origin of the Epistylis sp. have shown that they are derived from the soil and that, though originally present in very small numbers, they multiply rapidly on aeration. Once established in the tank, they stay on and continue to function until they are destroyed by one or other of the agencies mentioned above.

It would thus appear that the start as well as the efficient functioning of the activated sludge process is mostly dependent on Protozoa which are responsible, directly or otherwise, for not only sludge formation but also the attendant oxidation changes.

MIGRATION OF LEPIDOPTERA

LARGE-SCALE movements of butterflies have long attracted attention, as when in A.D. 1100 it was recorded, appropriately enough in a "History of Calamities", that swarms of butterflies were seen passing from Saxony to Bavaria. In 1508 "an innumerable swarme of whit butterflyes coming so thick as flakes of snow" was noted at Calais. It is clear that dense flocks, such as were common in the towns along the south coast of England in 1939–40, are not the result of modern conditions. The keen interest of Dr. C. B. Williams has led to much close study of the subject, on which an important paper has recently been published*. Dr. Williams claims that these movements are not a mere exodus from an area of food scarcity to a land of plenty, but a real migration in the sense that they are comparable with the familiar to and fro seasonal movements of birds. Evidence to this effect is particularly striking in the case of *Danaus plexippus*, the Milkweed butterfly or Monarch. This well-known species, of North, Central, and South America, occurs in different races with different, though overlapping, geographical distribution. The northern and southern races undertake large migrations, the central one does not. The northern race, *p. plexippus*, appears to have spread over a large part of the globe, and is the one which is occasionally captured in England. Its movements have been closely studied in the south-eastern United States, and it is clear that there is a definite northward movement in the spring, the last butterflies leaving Florida when the mean temperature rises above 75° F., and arriving in the north (reaching well into Canada) after the mean exceeds 50° F. There is definite evidence of their absence from Florida in the summer: they begin to return with corresponding temperatures.

Along the Pacific coast their behaviour has for some time been notorious, for their over-wintering sites are well known in California. The places chosen are dense groups of trees, preferably evergreens; almost every suitable locality is favoured, and the butterflies congregate at the same spot year after year in dense masses; these places are the termini of the return southward migration. The vexed question of whether the specimens taken in England have flown across the Atlantic or have travelled on ships cannot yet be decided. There is a record of several specimens caught by an officer of a ship outward bound from Glasgow; they were playing round the rigging about two or three hundred miles from British shores. But no records of large flights seen on the open sea, such as have been made for Pieridæ and the familiar Painted Lady, are to hand for *plexippus*, nor have they been recorded by lighthouse-keepers like some other migrants. Evidence of return migration for some other species is accumulating and is particularly clear in the case of *Dione vanillæ*: good evidence is increasing for nine other species, including the Silver Y moth, *Plusia gamma*. Dr. Williams discusses the evolutionary difficulty of understanding how the instinct to migrate is perpetuated if outward movements occur regularly without return flight. It is probable that the more closely the question is studied the more evidence will come to hand of return flight, and Dr. Williams says, "I can still point to no butterfly in which the absence of a return flight has been established beyond reasonable doubt".

The direction of these migratory flights is not primarily connected with the direction of the wind, for diagrams in which every recorded flight is plotted as an arrow head along points of the compass show little correlation with prevailing wind. It is concluded that the orientation of individuals flying in a cross-wind shows that they do appreciate, and allow for, wind direction, but there is no evidence that the wind determines the direction of any migratory flight. Nor can the direction be associated with the position of the sun: "When one has seen a migration continue steadily in one almost compass-true direction for several weeks on end, at all times of the day and in all weathers except perhaps heavy rain, it is difficult to believe that the direction of the sun's rays can have any importance." Very remarkable is an observation from Lake Ontario: a flight of *D. plexippus* was seen by an observer, fishing in Port Bay, a narrow southward arm of the lake. The butterflies were going south but at a short distance south of the observer they made a sharp left turn, crossed the bay, a distance of about a quarter of a mile, then made a right turn and headed south again.

Experiments to ascertain whether migrants appreciate, or orientate themselves in relation to, a magnetic field produced no evidence. It is not necessary, to establish the occurrence of a migration, that the butterflies should pass in noticeable swarms; the important point is the steady passage of numbers in one direction. Evidence of a migration was produced by observing about twenty butterflies passing in twenty minutes over a front of about one hundred yards. Such a movement, however, needs expert watching and repeated observation. It is thus quite possible that more evidence of return migration can be obtained. At the other end of the scale are snowstorm migrations in which the insects are too numerous to be counted even on a short front. In one flight of the African skipper *Andronymus neander*, it was estimated that five hundred per minute were crossing on a front of twenty-two yards. Attempts have been made to treat butterflies like migrating birds by marking and releasing many at a time. So far it has not been done on a scale large enough to give results, for extremely few recoveries have been made at any distance. Statistically, however, much can be learnt from the rate of disappearance of the marked individuals from the place where they were marked. Interesting evidence that migratory movements are due to widespread factors is provided by a statistical study of correlation between the movements in America and Europe of the well-known Striped Hawk moth (*Celerio lineata*) and the Painted Lady (*Vanessa cardui*). It appears that there is a tendency for large migrations to occur simultaneously in both continents. Similarly, within the British Isles there is some correlation between movements of different species of immigrants: thus *Plusia gamma* is usually abundant when *Vanessa cardui* is.

The destruction of migratory butterflies on a large scale by birds has often been recorded, and the dismembered wings of *Pieris brassicæ* were frequently noted in many parts of England during 1940.

The Insect Immigration Committee of the South-Eastern Union of Scientific Societies is responsible for the collection of evidence of movements, and more help is much needed. Only by the continued detailed study of large masses of data can many vexed questions be decided.

G. D. Hale Carpenter.

PASCAL TERCENTENARY CELEBRATION

IN 1642 Blaise Pascal, a Frenchman, invented the first calculating machine. The tercentenary of this event, which has had such a profound influence upon applied mathematics and physics, should appropriately have been celebrated this year in Paris. In order that the date should not pass unnoticed, a small committee was formed, under the chairmanship of Dr. L. J. Comrie, to arrange a commemorative luncheon followed by an exhibition of calculating machines. Other members of the committee were an eminent Frenchman of science now in Great Britain, Mr. W. Desborough and Mr. R. S. Nilsson, a Swedish engineer. The celebration was held on October 19 at the Connaught Rooms, London. The 120 guests who attended the luncheon ncluded those who design calculating machines, hose who make them, those who use them, and several members of the Fighting French, including an official deputation from General de Gaulle's headquarters.

After the toasts "The King" and "La France Combattante", the chairman recalled that it was in he year of Galileo's death and of Newton's birth hat Pascal invented the first calculating machine. A replica of this machine, made by Mr. Nilsson, stood on a table before him. Mr. Nilsson had also made a replica of the first English calculating machine, made by Samuel Morland in 1666, which was on show n the exhibition room. Many of those present, Dr. Comrie continued, would know of the great tercentenary held in Edinburgh in 1914 to commemorate the discovery of logarithms by Napier. Had it not been for the War, the French would certainly have eld a celebration on a similar scale in honour of Pascal. It was found that two people present, Prof. . Arnold Brown and Mr. F. E. Guy, had also attended the Napier tercentenary celebrations.

Dr. Comrie next welcomed the many distinguished rench men of science and representatives of the ighting French. He mentioned particularly Mme. Weill, a former associate of Mme. Curie, and Prof. Cathala, who had travelled from Scotland for the ccasion. The Norwegian Government and the Swedish Legation were also officially represented—reminder of the Swedish engineers Scheutz, Odhner, undstrand, Fridèn, Rudin and others, who had ontributed to the evolution of calculating machines.

Dr. Comrie then called on Prof. S. Chapman, resident of the Royal Astronomical Society, to ropose the toast "Blaise Pascal—the inventor of the st calculating machine", saying that Prof. Chapman had a special claim to propose this toast, since in his pacity as professor of mathematics at the Imperial ollege he had been one of the pioneers in introducing he study of calculating machines and numerical ethods into academic courses, and had also introduced them with conspicuous success into his own eophysical and other researches. Prof. Chapman's ddress is printed on p. 508 in this issue.

The reply was by Prof. René Cassin, Commissaire ational à la Justice et l'Instruction Publique de la rance Combattante. He thanked the committee, on half of the French in Great Britain, for their enterprise in arranging this celebration in honour of Pascal. e stressed the versatility of Pascal's genius: at e age of nineteen, when he invented the calculating achine—essentially a practical instrument—Pascal was already well known in the realm of pure mathematics. His perseverance with this invention helped one to appreciate more fully the character of Pascal. He had to fight not only ill-health but also the ignorance of his time, for his conception far outstripped the mechanical experience and ability of those to whom the work was entrusted. It was not until Pascal had made more than fifty models that he achieved his final design.

The invention of the calculating machine illustrated Pascal's extraordinary creative imagination, allied with mathematical genius and precision, and tempered with critical penetration. These qualities were characteristic of the man throughout his life. Prof. Cassin spoke of Pascal's conviction, also candidly expressed in his letter to Queen Christine of Sweden, that learning was greater than the power of princes—"Toute notre dignité consiste en la pensée. Travaillons donc à bien penser : voilà le principe de la Morale". It was stimulating to remember this defence of liberty of thought at a time when political tyrants tried to turn men into machines incapable of thinking, forcing upon those in their power their fanatical ideas. The spirit of Pascal was an inspiration of those who strove to restore to France her freedom.

Prof. D. R. Hartree, whose task was to propose a vote of thanks to the speakers, asked to be allowed to include Dr. Comrie in his remarks, saying that the success of the gathering was in great part due to his chairmanship. He was glad of the opportunity of paying his own tribute to Pascal, not only as the inventor of the calculating machine but also as the worthy representative of the spirit and genius of the French people.

After the luncheon a small exhibition, which was open to the public, was held in an adjoining room. Various types of hand and electric calculating machines and models were shown, and demonstrators explained their working and applications to visitors. Two short lectures were given, one by Dr. Comrie on "Mathematical Gymnastics with Calculating Machines", and the other by Mr. Nilsson on "A Description of Calculating Machine Mechanisms".

M. E. P.

EVOLUTION IN SOCIETY

SIR WALTER LANGDON-BROWN, in his presidential address to the British Social Hygiene Council on October 12, discussed "The Place of Social Biology in the Sciences". He indicated that the interdependence of all life is shown by the fact that at every stage of the journey, from the apparently inert mineral to the conscious intelligent being, the 'laws' governing the lower levels apply to the higher, though the latter also develop new laws of their own. The most complex plant has to obey the ordinary laws of chemical combination as faithfully as has the soil from which it springs, but in addition it has acquired the capacity for building up food reserves by photosynthesis. Animals have acquired kinetic energy for which they are dependent on the potential energy of the plant, and they can effect, through catalysts, chemical reactions at ordinary temperatures which can only be imitated in the laboratory under conditions incompatible with life. The same holds for the progressive stages from simple reflex action through instinct to intelligence. At each step something fresh is added to the old law. Presumably this applies also to the still higher values of life. Yet though man lives by this balance of Nature, he is too apt to act like a bandit of the soil, converting fertile lands into deserts. The urgency of this matter is at once obscured but really intensified by urbanization.

Man is a gregarious animal and cannot live in isolation without dire injury to himself. Here biology and sociology are at one. Maudsley said "there could not be a greater danger to the balance of any mind than to be exempt from the bonds and pressure of the surrounding social system". Dictators illustrate that truth. Sir Arthur Keith has directed attention to two opposing tendencies in life—one the general demand of evolution for enlargement of the unit, the other the species-making impulse to segregate a particular type. The former makes for internationalism, the latter for nationalism. The present fanatical outbreak is the frightened and pathological response of the species-making impulse faced by the imperious demands of evolution. The nervous system was developed to allow of rapid co-operation between the various organs of the individual, and rapid communication is essential to the co-ordination of the complex civilization of to-day. The present issue is clear-cut: Do individuals exist for the State or the State for individuals? It is quite possible to win the war and yet to lose on that issue.

The human unit which must be conserved is the family. The child must be confident of security in one person and that person the mother. Mother love was the first moral value to emerge. Father love came later with the longer dependence of the young in the higher forms of life. Children of the same parents differ not only innately in their genes, but, as Adler pointed out, in their environment according to their position in the family, as can be seen by comparing the different reactions of the eldest, the second and the youngest. It is inevitable that for good or ill what the child makes of life will largely depend on the family life he has experienced. The serious misfits are usually the products of unhappy homes. To quote Prof. Wood-Jones, "if we realize that we . . . like all creatures have a part to play in a cosmic process greater than any individual, then we are likely to take a humbler and more balanced view of ourselves".

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Saturday, October 31

INSTITUTE OF PHYSICS (ELECTRONICS GROUP AND MIDLAND BRANCH) (at the College of Technology, Rugby), at 2.45 p.m.—Dr. D. Gabor: "Electron Optics".

ASSOCIATION OF SCIENTIFIC WORKERS (at the Royal Photographic Society, 16 Princes Gate, South Kensington, London, S.W.7), at 3 p.m.—Exhibition of "Photography in Science and Industry" (to be opened by Sir Robert Watson Watt, F.R.S.).

Tuesday, November 3

KODAK, LTD. (at Kodak House, Kingsway, London, W.C.2), at 2 p.m.—Exhibition of "Photography's Part in the War" (to be opened by the Rt. Hon. Lord Brabazon of Tara).*

SOCIETY OF CHEMICAL INDUSTRY (JOINT MEETING OF THE FOOD GROUP WITH THE AGRICULTURE GROUP) (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 2.30 p.m.—Dr. G. H. Bates: "Increasing the Food Output of Great Britain".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 3 p.m.—Sir James Jeans, O.M., F.R.S.: "Evolution in Astronomy", 1.*

Wednesday, November 4

ASSOCIATION OF SCIENTIFIC WORKERS (at the Royal Photographic Society, 16 Princes Gate, South Kensington, London, S.W.7), at 6.30 p.m.—Dr. D. A. Spencer: "Photography as a Tool".

Thursday, November 5

TOWN AND COUNTRY PLANNING ASSOCIATION (in the Lounge of the Y.M.C.A., Central Buildings, Great Russell Street, London, W.C.1), at 1.15 p.m.—Mr. G. A. Jellicoe: "Landscape Architecture and Planning".

INSTITUTION OF ELECTRICAL ENGINEERS (JOINT MEETING WITH THE INSTITUTION OF MECHANICAL ENGINEERS) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. J. N. Waite: "Coal for Steam Raising".

Friday, November 6

PHYSICAL SOCIETY (in the Lecture Theatre of the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 4.30 p.m.—Prof. H. R. Robinson, F.R.S.: "Rutherford, Life and Work to the Year 1919, with Personal Reminiscences of the Manchester Period" (First Rutherford Memorial Lecture).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. W. V. Mayneord: "The Measurement of Radiation for Medical Purposes".

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Lord Dudley G. Gordon: "Recent Developments in Refrigeration" (Thomas Hawksley Lecture).

ASSOCIATION OF SCIENTIFIC WORKERS (at the Royal Photographic Society, 16 Princes Gate, South Kensington, London, S.W.7), at 6.30 p.m.—Mr. E. D. Eyles: "Some Applications of High-Speed Photography".

Saturday, November 7

BIOCHEMICAL SOCIETY (in the Department of Organic Chemistry, Imperial College of Science and Technology, South Kensington, London, S.W.7), at 11 a.m.: Discussion on "The Theory and Application of Chromatographic Methods to Biological Problems".

Saturday–Sunday, November 7–8

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX (at the Royal Society, Burlington House, Piccadilly, W.1).

Saturday

At 11 a.m.: Annual General Meeting. At 12 noon: Sir Richard Gregory, Bart., F.R.S.: "International Systems and Standards".

Sunday

At 10.30 a.m.: Symposium on Microfilm.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on o before the dates mentioned:

LECTURER IN MECHANICAL ENGINEERING with some knowledge o Electrical or Automobile Engineering—The Principal, College o Technology and Commerce, Leicester (November 7).

TEACHER OF MECHANICAL ENGINEERING—The Principal, Wolverto Technical College, Wolverton, Bucks. (November 7).

INSTRUCTOR IN ENGINEERING WORKSHOP PRACTICE at the Llanell Mining and Technical Institute—The Director of Education, Education Department, County Hall, The Castle, Carmarthen (November 7)

LECTURER IN MECHANICAL ENGINEERING at the Constantine Technical College—The Director of Education, Education Offices, Middlesbrough (November 9).

HEAD OF THE MINING DEPARTMENT of the Chesterfield Technica College—The Clerk to the Governors, Technical College, Infirmar Road, Chesterfield (November 9).

A MACHINERY OFFICER, A DRAINAGE OFFICER, and AN ASSISTAN DRAINAGE OFFICER—The Executive Officer, Hampshire War Agr cultural Executive Committee, The Castle, Winchester (November 9

DEMONSTRATOR IN THE CHEMISTRY DEPARTMENT of the Londo (Royal Free Hospital) School of Medicine for Women (at the Unive sity College of the South West, Exeter)—The Warden and Secretar Reed Hall, Streatham Drive, Exeter (November 19).

LECTURER IN MATHEMATICS—The Principal, Stockport College fc Further Education, Stockport.

REPORTS and other PUBLICATION

(not included in the monthly Books Supplement)

VENEREAL DISEASES: A SOCIOLOGICAL PROBLEM

THE Government is concerned about the present increase in venereal diseases throughout Great Britain. While the majority of us outside the medical profession, and quite a number of medical men themselves, treat the subject as we do, that is, taboo, the announcement that such an increase is taking place is no occasion for surprise; for, by implication alone, that is, without data, we are bound to conclude that with the present war-time change in conditions, accompanied by scarcely any change in the general attitude towards venereal disease as a social problem of the first magnitude, the whole problem is almost certain to loom up as a challenge to public health, leaving us concerned and confused.

Let us now look at the data as recently presented by Sir Wilson Jameson, chief medical officer of the Ministry of Health. Before the War, venereal disease in Great Britain was steadily decreasing; in fact, hitherto, compared with other countries, we had a very good record. In 1931, more than 9,000 cases of syphilis contracted during the year attended clinics in England and Wales. In 1939 this figure had fallen to about 5,000—a record reflecting credit on the medical research and services of the country. Last year, the number of new infections of syphilis among the civilian population treated at clinics (to which the great bulk of cases of syphilis go for treatment) was 7,332. The number of new cases of gonorrhœa is not known precisely because quite an appreciable number are treated by private medical practitioners, and venereal diseases are not notifiable. Roughly speaking, however, there are eight new infections of gonorrhœa to every one of syphilis. Therefore there was a total of nearly 70,000 new venereal infections among civilians last year. There were 5,000 cases of syphilis infection among civilians in 1939, 5,600 in 1940 and 7,300 in 1941. If to this be added the infections in the Services, there has been an increase of about 70 per cent infections in Great Britain since the War began. This need not necessarily give cause for alarm, because a certain increase is inevitable in present conditions. But it does present food for thought. Are we as a community approaching the problem at the right angle? Is not the long-distance view the better one to take in this case?

It is a matter for reflection that many men of science might immediately respond: 'What has this to do with us? It is the concern of our medical colleagues.' On closer consideration, however, we must admit that it is not only a matter for the concern of men of science, especially biologists and educationists, but also it is all the more serious because so many men of science are ignoring this fact. The whole problem is a sociological one of the first magnitude, and might well become more serious unless more public-spirited people help to grapple with it. It is useless to adopt, as we have tended to do in the past, a policy of *laisser-faire*, and it is certainly neither fair nor wise to leave it to the Government, for many members of this or any other Government of the past probably need as much enlightenment as the rest of us. It is undoubtedly a problem for Government, local authorities, Church, medical men, men of science, educationists and others, all working together in enlightened harmony.

Here we are concerned only with men of science—especially biologists and educationists. What have they done and what are they doing to meet a situation which has really been facing us for years, though now in a more acute form, as is usual in war-time ? Medicine offers much, and, in fact, is probably doing as much as can be expected of it. Sir Wilson Jameson has revealed that in England and Wales there are two hundred treatment centres, mostly at hospitals, with skilled staffs and equipment. More treatment facilities have been set up to meet war-time contingencies. If everyone who contracts one of these venereal diseases would only seek skilled treatment at the earliest possible stage, and continue it, *the problem would be reduced to manageable proportions within a few months.*

Can we ask much more than this of the medical men ? Being the men on the job, they must inevitably realize the seriousness of the problem. This has been so since long before the War. But even the medical men have been too prone to look upon the problem rather as an exclusively medical, or we might say, technical one. Now they are beginning to realize that the whole question must be considered from more angles than that of physic or public health. The Central Council for Health Education*, which is composed almost entirely of public-spirited medical men, under the chairmanship of Dr. C. Hill, the capable and energetic deputy secretary of the British Medical Association, and inspired by the presidency of no less a social leader than the Archbishop of Canterbury, is attacking the whole issue as a sociological problem of the utmost importance. Lectures throughout the country by an authoritative and well-trained staff, films and pamphlets on health subjects (paying special attention to venereal disease) all come within the ambit of the Central Council, which works in close liaison with the Ministry of Health. Thus are medical men courageously tackling, in a manner which brooks little criticism, a problem which otherwise might well seriously undermine the physical, mental and moral health of the country.

But this War, like the last though even more so, has brought into the limelight a serious sociological defect that has really been evident to those who would see for a very long time. We, as men of science, may leave it to the Ministry of Health, the Central Council for Health Education, and other authorities to deal with the exceptional and very difficult health problems which have become intensified in a country at war. But what of the future ? Is it fair to leave it all to the medical profession ? And do the majority of medical men themselves realize what is the fundamental root of the entire problem ? Are medical men and their organizations responsible for the deplorable state of the country (and indeed the whole world) so far as venereal disease is concerned ? If we refer back to the claim that the whole problem "would be reduced to manageable proportions within a few months", we must give a negative reply to all these questions.

It is the opinion of the Ministry of Health that the first requirement in combating the spread of venereal disease is 'open discussion'. This seems very reasonable, for here we have local authorities and their medical organizations, institutes, advisers and practitioners, offering free and confidential treatment, yet the whole of this valuable social service is handicapped by what Sir Wilson Jameson calls "this misguided secrecy". "Because of an old tradition of 'hush-hush' on the matter, the public does not know what it ought to know." It is not a question of the knowledge at the disposal of the medical profession, but more a problem of the application to society of already well-known discoveries. There is no need to make any startlingly new medical discoveries ; *we have the information needed to deal with venereal diseases.*

Clearly there is something very wrong with a community which is suffering from a blot on its public health system, has the wherewithal for erasing it, yet fails to do so. Educationists and men of science—especially biologists—must be aware of the difficulties of their medical colleagues ; they must therefore show their awareness and come forward and do their share more openly. The public must be informed, of course ; but there lies the difficulty. The 'hush-hush' tradition is an intolerable handicap ; this "misguided secrecy" is a ludicrous, almost Gilbertian, blockade to progress. A medical practitioner can discuss the most intimate details of a case of pregnancy with a woman and still remain a gentleman ; why cannot he be given the same chance in this connexion ?

Much is due to *laisser-faire*, much to the ignorance of those who in any event never appeal to medicine or science until something goes wrong—and sometimes not even then ; but one major cause of the difficulty can be ascribed to those present-day people who resent open discussion (consequently public enlightenment) of a quite understandable problem. Venereal disease can scarcely be claimed to be a topic for the drawing-room, but then neither are cancer, tuberculosis, or even nutrition, except perhaps war-time food rationing. Therefore, whether those members of the community who pursue the policy of the ostrich or the hypocrite are to be appeased or ignored is a matter for the State authorities. As Sir Wilson Jameson has said, we shall never combat and eventually bring this scourge under control by running away from it, by shutting our eyes to its existence, by refusing to discuss it, or by withholding from young people information regarding its dangers. We have the knowledge and the facilities we need. Early diagnosis and early skilled treatment are available, and everyone should be made aware of the prevalence of venereal disease, how it is contracted and how it can be cured. There must be no more secrecy.

The fact that the State is in this quandary is one of general, and therefore much wider, responsibility. It is surely a matter of education—general education. If the ordinary man had developed, through the formal education of his earlier years, the correct frame of mind and a rational attitude towards life, it would be possible to discuss with him the seriousness of venereal disease as easily and frankly as it is to warn him against sneezing in public. To over-ride all this should be the ultimate, and therefore fundamentally the most important aim, in the whole problem; the immediate aim—curing of those afflicted—is the concern of medical men. If the educationist gave his charges the best and most liberal education, he would hand over to society broad-minded, rational citizens who would give no special concern to health authorities so far as venereal or indeed other diseases are concerned. This is not to suggest that the subject of venereal disease should ever be discussed or even mentioned in our schools; it would be a sad day if and when this ever became necessary.

---

* Tavistock House, Tavistock Square, London, W.C.1.

Most medical men and many other biologists can discuss with their colleagues the problems involved in connexion with venereal disease without turning a hair, but they could not do so without an acute feeling of embarrassment with non-biologists, nor indeed with many who have had a certain amount of biological training. Here, therefore, lies a strong argument in favour of every child being given a broad biological background during his school years, and this should begin long before he personally attains physical sexual maturity. During any complete survey of the field of biology in our schools, the elements of human reproduction should receive consideration in their logical place in the scheme of the curriculum. Human reproduction should not be left, as it so often is, to implication from the study of reproduction in the rabbit or the frog. By this, we do not for one moment suggest that sex should be emphasized in any way, and certainly venereal disease should never be considered, any more than a teacher would discuss in school the details of an operation for appendicitis. The general concepts of healthy living would, however, inevitably find a place in the curriculum. If a man or woman had been correctly trained in the elements of general biology, then discussion of venereal disease in later life (if it arose out of necessity as it has now) would not give cause for embarrassment, and it surely would never have to take place, metaphorically speaking, behind closed doors, though, for many obvious reasons, a certain amount of secrecy in each individual case is desirable.

Many of our medical men realize all this. For the first time, on October 23, Sir Wilson Jameson broadcast a thoughtful and well-balanced talk through the B.B.C. to the British public on the questions of tuberculosis and venereal disease. So also is the Central Council for Health Education acting vigorously. This Council is taking both the immediate and long-distance view. For the latter reason, the Council has established an Educational Advisory Committee. Let it be said at once that this Committee is not concerned especially with the problems of venereal disease. It is composed of well-known educationists and representatives of educational organizations, biologists and medical men; and its main function is to advise the Central Council on questions of general biological teaching, but with special reference to healthy living. Sex, and certainly venereal disease, are never specially picked out during its deliberations; in fact, there is not one specialist in venereology among its medical members. Its function is, through the machinery of the parent body, to assist, advise and criticize wherever necessary, so that there may eventually be established throughout Great Britain a better and more balanced training in biological principles, chiefly in the schools. Though the Committee is in no way influenced by the Board of Education, the Board is represented at it. The Ministries of Health and Food also send observers. The Committee feels that through its efforts, with others, in the years to come our citizens will attain a sense of real values and will better be able to face squarely and fearlessly any problems of public health, well-being and progress which may arise.

The present rise in incidence of venereal disease is, as in the past, mainly the result of the absence in our men and women of a biological attitude towards, and an informed view of, life. It is partially the results of faulty training in the schools. The same can be said of nutrition and other aspects of human biology. It is impossible to teach and guide the public completely and satisfactorily because of this ill-informed attitude of the public itself. If our men and women were more cognizant of the facts of the human body and human relations, they would develop a more positive attitude towards human ailments and frailties, and the negative influence of other drawbacks in our society would then largely be eliminated. If our citizens of to-morrow are given a broad outlook in biology, then many of our sociological defects, such as venereal disease, the pernicious influence of quack medicines, malnutrition, the lack of physical training, and so forth, will either disappear entirely or at any rate will not be aggravated by the evil influence of 'hush-hush', or allowed to exist because of igrorance on the part of the general public; further, they will be brought into a sane field of vision and action.

As things are, one Government after another finds itself faced with the need for legislation and organization of many factors concerning public well-being which should never arise. As Sir John Orr, one of the members of the Educational Advisory Committee, claims, malnutrition is one of the major issues of national and international policy and will become even more so. The same may be said of other aspects of public health. Once educationists in general, and biologists in particular, have got down to their duties more in keeping with up-to-date principles of education, then we shall be well on the road towards that desirable goal where we can naturally and sanely consider *all* problems of human biology and sociology in open discussion, and thus set in motion the machinery for combating the enemies of individual and public health and social progress—machinery meticulously constructed by medical, scientific and educational research and oiled by public sympathy, goodwill and confidence.

THE MANUSCRIPTS OF C. W. SCHEELE

Carl Wilhelm Scheele

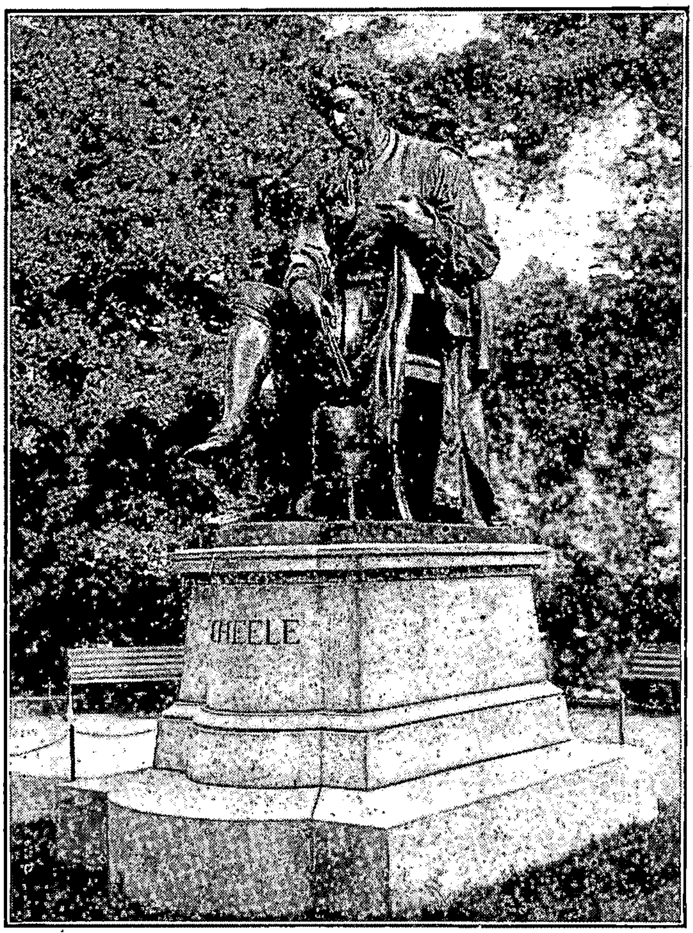
Manuskript 1756–1777. Tolkning av C. W. Oseen. Pp. vi+173. Manuskript 1756–1777. Ordnade av C. W. Oseen. Ljustryck. Pp. v+182. (Stockholm: K. Svenska Vetenskapsakademien, 1942.)

JUST as Edmund Spenser is called 'the poet's poet', so Carl Wilhelm Scheele merits the title of 'the chemist's chemist'. Lacking all formal training in science, he was instinctively the perfect investigator. In experimental technique, Campbell Brown has remarked in his "History of Chemistry", Scheele has never been surpassed. "His discoveries were the result of carefully planned series of experiments, and he left nothing in doubt where experiment could decide it. He is a model to all who are engaged in chemical research."

Born in 1742 at Stralsund, the chief town of what was at that date Swedish Pomerania, Scheele was apprenticed to an apothecary in Gothenburg at the age of fourteen and spent practically the rest of his all-too-short career—he died at Köping in 1786—as a pharmacist in Sweden. Struggling always against poverty and ill-health, he planned and performed his chemical experiments day after day and year after year in the isolation of provincial shop-laboratories, knowing little (except through correspondence) about the work of his contemporaries in other countries and remaining himself almost completely unrecognized until 1777, when he published his "Chemical Treatise on Air and Fire". He literally lived for his research work, as may be seen by an extract from a letter which he wrote to his friend Gahn in 1775:

"Oh, how happy I am! No care for eating or drinking or dwelling, no care for my pharmaceutical business, for that is mere play to me. But to watch new phenomena—this is all my desire, and how glad is the enquirer when discovery rewards his diligence; then his heart rejoices."

Among the numerous discoveries which rewarded Scheele's diligence and made his heart rejoice were two of really primary importance—oxygen and chlorine. Priestley, it is true, was the first to announce the discovery of oxygen, and he is commonly given the principal credit therefor, but we know now from Scheele's note-books that he had prepared the element systematically in several different ways prior to the more famous, but comparatively casual, experiments of Priestley in 1774. After Scheele's death, the Royal Swedish Academy of Sciences commissioned its secretary, J. C. Wilcke, to deliver a memorial address, and the manuscripts which Wilcke obtained from Scheele's widow to assist him in the preparation of this address were afterwards deposited in the archives of the Academy. Fifty years ago, certain of these manuscripts were published in a stately volume by A. E. Nordenskiöld: "Carl Wilhelm Scheele. Correspondence and Laboratory Notes" (Stockholm, 1892). As Dr. Leonard Dobbin, in his valuable book, "The Collected Papers of Carl Wilhelm Scheele" (Bell and Sons, 1931), has stated, the introduction to this volume, together with Nordenskiöld's annotations and additional matter, provides a wealth of interesting biographical and other information, much of which is not included in earlier biographies. Nordenskiöld concludes his own biographical sketch with the following paragraph: "The picture which biographers have given of Scheele as an investigator is incomplete. It is only by the aid of the letters and laboratory records here presented that we can obtain a grasp of the insatiable thirst for knowledge which impelled him to separate and to examine in his flasks, retorts and crucibles everything that came into his hands; of the number and importance of his chemical discoveries; of the range of the experiments upon which every communication that appeared in print was based; of the discernment with which even the most inconspicuous phenomena were observed and utilized as guides in the elucidation of new truths; and of Scheele's true significance as a real pioneer of scientific chemistry."



CARL WILHELM SCHEELE

The statue stands in Humlegården, one of Stockholm's many beautiful parks. It was modelled by J. Börjeson and unveiled in 1892, in commemoration of the sesquicentenary of Scheele's birth.

It now appears, however, that Nordenskiöld's picture is itself extremely incomplete. Fru Elin Bergsten, who was entrusted with the task of deciphering the manuscripts, was a skilful palæographer but no chemist, and had perforce to leave no small portion of their contents unexplained. It is to fill up the extensive gaps in Fru Bergsten's transcriptions that the two volumes here under review are devoted.

The immediate urge for their publication is twofold. First of all, there is the desire of the Royal Swedish Academy of Sciences to celebrate in appropriate manner the bicentenary of Scheele's birth in 1742 (the exact date is December 19). The second factor can best be explained by direct translation from Prof. C. W. Oseen's preface:

"Modern methods of waging war threaten all memorials of civilization with annihilation. No other salvation from this danger is offered to the strongest of such memorials, old buildings, than chance may bring. There is, however, one method of saving the weakest and the most easily destroyed, —the written page: not quite certain, but almost certain. Reproduction of a sufficient number of copies and dissemination of these copies in a sufficient number of different places ensures, with practical certainty, that some one of the copies will escape destruction.

"Have these manuscripts of Carl Wilhelm Scheele such value for the present and future generations that their preservation in a world of destruction can be justified? The answer is that if these manuscripts can only be correctly dated, then we shall be able to fix the dates of Scheele's discoveries. An attempt in this direction was made by A. E. Nordenskiöld about 1890, but such a task is too much for one man; it demands the collaboration of all those scientific men who are interested in the subject. To render such collaboration possible is one of the objects of this publication of Scheele's manuscripts.

"Is it, now, so important to know, *when* Scheele made his discoveries? This publication is based on the assumption that it is important, both for us and for those who will come after us, to know the past, in other words on the assumption that civilisation will persist and not be destroyed."

Therefore Sweden, fortunate enough so far to have escaped the 'crocodile', safeguards the human race against the still imminent wanton destruction of her scientific treasures by presenting these priceless manuscripts to the world at large "in the war-year of 1942". It is a noble project, and it has been nobly accomplished. One of the two volumes comprises 182 pages of beautiful photographic reproductions of the manuscripts themselves, arranged by Prof. Oseen. In the other volume, Prof. Oseen has "decoded" Scheele's crabbed conglomerations of alchemical and pharmaceutical signs, dog-Latin and contracted German, into modern print. How onerous the task was, and how conscientiously and skilfully it has been carried to completion, can be fully appreciated only by careful comparison of corresponding sections.

In thirteen pages of notes at the end of the second volume, Prof. Oseen discusses in a scholarly manner certain of the chronological problems involved, particularly with respect to two of the most important oxygen manuscripts, No. 43 and No. 52. His conclusions regarding the latter differ significantly from those of Nordenskiöld, and the arguments presented are of considerable interest in indicating the general line of attack which must be followed in order to arrive at the final goal—the authoritative dating of all Scheele's manuscripts. This pleasant duty will undoubtedly attract the keenest collaboration of chemical historians in all countries in the more tranquil future.

JAMES KENDALL.

PHOTOGRAPHIC IDENTIFICATION OF TIMBERS

Studies of the Identification of Timbers

With a Note on the Seasoning of Wood. By Alexander L. Howard. Pp. v+110. (London: Macmillan and Co., Ltd., 1942.) 36*s*. net.

MR. ALEXANDER L. HOWARD'S well-known and much-used book entitled "A Manual of the Timbers of the World", of which the last edition was published in 1934, contains no illustrations of the structure of wood. In order to remedy this defect, and to facilitate the identification of timbers, he has now published a new companion volume, of which the principal contents consist of 504 photographs of transverse sections of different kinds of wood magnified by ten. Each illustration is about 3 cm. × 5·5 cm. and therefore represents an actual cross-sectional area of just over 1½ sq. cm. of wood. All these illustrations were prepared by Mr. G. R. Keen from microtome sections which he himself cut from Mr. Howard's own collection of authentic specimens. The work entailed must have been very considerable, and to have produced a book of this kind after three years of war shows no small enterprise on the part of all concerned.

One must confess, however, that the result is somewhat disappointing. In the first place the illustrations are of very variable quality; while some of them are reasonably satisfactory, others fail to give a fair representation of the timber concerned. This applies especially to Nos. 42, 57, 67, 113, 121, 136, 278, 359, and 370, to mention a few of the less inspiring. Illustrations more like those in H. P. Brown's "Atlas of Commercial Timbers of the United States" or Pearson and Brown's "Commercial Timbers of India" would have been far more useful. As, moreover, timber merchants generally have to examine a transverse surface of a solid piece of wood cut with a sharp knife, rather than sections, it would have been far better to photograph the actual surface of the wood. Only a highly skilled photographer could secure the best possible results by this method, but the work entailed would have been well worth while. It is a great pity that Mr. Howard went to the trouble of preparing a special set of sections when comprehensive collections of microscopical slides already exist at several institutions where the identification of timbers and the preparation of photomicrographs are matters of routine. By collaborating with one or more of these institutions a better result could have been achieved.

It is, besides, impossible to portray all the possible variations in wood structure which occur within a single botanical species in a solitary photograph of a cross-sectional area of just over 1½ sq. cm. This is one of the reasons why the book does not always enable the user to identify the woods with certainty. If verbal descriptions as well as the illustrations had been included, some idea of the variations which are to be expected in a single kind of wood could have been given. Another difficulty is that many timbers, especially among the softwoods, can be identified with certainty only by characters visible with a compound microscope. By relying on lens characters alone and comparing them with the illustrations in this book, it would, for example, be quite easy to confuse the timbers shown in Figs. 241, 314 and 453 respectively. The botanist and forester will also object to the curious alphabetical sequence in which the timbers are arranged; vernacular, trade and botanical names having been used quite indiscriminately. The separate indexes of botanical and other names at the end of the book help to overcome this defect. In many instances the botanical names are not recorded at all, which is to be deplored in a work of reference. This curious arrangement is similar to that previously adopted in "A Manual of the Timbers of the World".

It is rather surprising in a book on timber identification to find that the only text, apart from the preface, consists of some forty pages describing the conversion and seasoning of timber. This, however, provides a useful and authoritative summary.

Taken as a whole, the book will be found helpful in identifying timbers, especially by those who are casually interested or to whom a collection of authentic specimens is not easily accessible. It also enables a rapid preliminary comparison to be made whenever a specimen is received for identification. It will, however, be desirable to consult other sources of information when precise and accurate identifications are required; for example, when settling legal disputes.

If Mr. Howard had taken some of his many scientific friends more fully into his confidence before publishing this book, a notable addition to our applied botanical literature might have been achieved. A book based on his long practical knowledge of the trade, combined with that of an experienced botanist or forester, would have been well worth while.

C. R. METCALFE.

HYDROGEN IONS IN PURE AND INDUSTRIAL CHEMISTRY

Hydrogen Ions

Their Determination and Importance in Pure and Industrial Chemistry. By Prof. Hubert T. S. Britton. (Monographs on Applied Chemistry, Vol. 3.) Third edition, thoroughly revised and enlarged. Vol. 1. Pp. xix+420. 36*s.* net. Vol. 2. Pp. xix+443. 36*s.* net. (London: Chapman and Hall, Ltd., 1942.)

THE appearance of a third edition of Prof. Britton's well-known text-book on "Hydrogen Ions" will be welcomed by those physical chemists who are concerned with the control of analytical and industrial processes by means of *p*H measurements. The ten years which have elapsed since the publication of the second edition have seen a large increase in the original literature of the subject and this has necessitated a considerable increase (some 274 pages) in the size of the book and its division into two volumes. The book is well printed on good paper and shows few signs of war-time austerity, with the exception of the price, which has increased nearly 200 per cent: perhaps this is only the shape of things to come.

The importance of *p*H measurements in analytical operations, electro-deposition and tanning processes, in the sugar, paper, brewing, dairy and explosive industries, in baking, water purification and sewage disposal, in agriculture and the textile and dyeing industries, in ore flotation, etc., fully justifies the appearance of this new edition, for it is a valuable contribution to our technical sinews of war. The book is a mine of information particularly concerning the practical aspects of *p*H measurement, and the author draws freely on his extensive practical experience in his critical assessment of the experimental methods described. The numerous tables of information and practical notes make the book a valuable *vade mecum* for all concerned with *p*H measurement.

Besides the more technical aspects of hydrogen ion measurements, the author discusses subjects of more academic interest; for example, the ionization of dibasic and poly-basic acids, the Lowry–Brønsted theory of acids and bases, etc. The new edition also includes a chapter on oxidation-reduction processes, including the use of redox indicators.

The book has been written primarily for those concerned with the industrial aspects of physical chemistry. Those concerned with the more theoretical aspects of the electrochemistry of solutions will find in the book much to interest and instruct them, but some will perhaps be a little dissatisfied with the treatment of the more modern aspects of the subject. At what stage in his course should a student be introduced to the newer theories of electrolytic dissociation? This question, no doubt, exercises the minds of many teachers. Prof. Britton has adopted in his book, what is the common practice, of first tentatively applying the Arrhenius theory to strong electrolytes and only at a much later stage, half-way through the first volume, introducing the activity concept. This procedure is not altogether satisfactory as it necessitates frequent qualification of statements in the earlier part of the book, a procedure which must cause confusion to a reader not already familiar with the subject.

So much has already been written of *p*H and buffer solutions which is based on the erroneous assumption of Arrhenius concerning the dissociation of strong electrolytes that considerable confusion would be caused by changing to the more satisfactory thermodynamic basis. The standard of reference of any potentiometric scale is an arbitrary one, so why change it, even if the older definition of the standard hydrogen electrode is not satisfactory? The author gives these reasons (pp. 292–294) for his retention of the original definition of *p*H, and many would agree on grounds of expediency. The criticism of the modern theory given as an additional reason for retention of the older concepts will not meet with such wide agreement, for the statement concerning the impossibility of determining single ion activity coefficients is perhaps a little unfair; a very similar criticism can be made against the concept of the single electrode potential used by the author.

The chapter on the Debye-Hückel theory has been largely re-written, but room has not been found to include an account of the success which has attended the application and extension of these ideas to the interpretation of the electrical conductivity of strong electrolytes and the effect of high potentials and high frequencies on the conductivity. No mention is made of the interesting work of Wien and of Onsager on the effect of high potentials on the dissociation of weak acids, nor is the heavy hydrogen ion discussed. Reasons of space, no doubt, made it necessary for the author to circumscribe his field.

Another edition of this book will certainly be called for in the not too distant future, and it will no doubt be necessary for Prof. Britton to put the chemical community more in his debt by enlarging his book still further.

H. L. RILEY.

DARWIN MANUSCRIPTS AND LETTERS

GIFTS TO CAMBRIDGE AND TO DOWN HOUSE

A GENEROUS and timely grant from the Pilgrim Trust has enabled the owners of certain important manuscripts of Charles Darwin to present them, some to the University Library at Cambridge and some to the British Association for preservation at Down House. The gift includes the manuscript of Charles Darwin's autobiography, the manuscript of the diary of the *Beagle*, with the field note-books from which it was compiled, most of the manuscript of the "Origin of Species", the manuscript of "Movement in Plants", "Climbing Plants", and other works ; correspondence with Wallace, Samuel Butler, Huxley and other contemporaries ; a number of personal papers and of memoranda relating to Down ; and a collection of pamphlets, some with his annotations. It was in 1842 that Charles Darwin went to live at Down House. The first sketch, in his handwriting, of his species theory, written in 1842, is included in the gift.

A wise division of these manuscripts has been made. To the Library at Cambridge go the papers which, as will be seen, possess the highest possible value to the history of scientific research—papers which generations of future students may well wish to reinvestigate. To Down House, Darwin's home from 1842 until his death in 1882, now held by the British Association as a national memorial under the gift of Sir Buckston Browne, there return those priceless relics which will be most appropriate for those who visit the place to see—"exhibitable objects", as they were termed by one of those responsible for the division. Down House is closed to the public now, but when it becomes possible to reopen it, the collection of Darwiniana, viewed before the War by some seven thousand visitors annually, will be found to be enhanced by additions of unique personal interest.

A few examples only can be chosen for mention here out of the large mass of material comprised in the gifts. Among the documents destined for Cambridge are, foremost, sketches of "The Origin of Species", dating from 1842 and 1844, and manuscripts of chapters of the work as originally planned, and before the work was abstracted for publication in 1859. There is a fair copy of a draft, annotated by Darwin and Hooker, on "Varieties in Large Genera". There are manuscripts, complete or partial, of, or relating to, the "Expression of the Emotions", "The Movements and Habits of Climbing Plants", the "Cross- and Self-fertilization of Plants", "The Power of Movement in Plants", and other works. There are also manuscripts of a number of short papers communicated to scientific societies and periodicals.

Numerous scientific notes, in books or on loose sheets, are included in the collection. Some are very early, dating from Darwin's short period at the University of Edinburgh as well as from his Cambridge days. Among the material of later date is much that relates not only to the major works but also to other investigations—the names of the parallel roads of Glenroy and of Salisbury Craigs appear ; glacial studies, coral reefs, Peloria, phyllotaxy, pangenesis, embryology, hybridism, are a few among many subjects. Memoranda for later editions of "The Origin of Species", "The Descent of Man", "Coral Reefs", "Climbing Plants", "Orchids", "Cross- and Self-fertilization" are included.

In this group of documents there are also the small brass-clasped notebooks kept during the voyage of the *Beagle* and the classified scientific notes made up from these : it is to be noticed that as each page in the notebooks was collated it was crossed through. The very records of observations and incidents made during that arduous voyage, often, it must have been, in circumstances of difficulty and stress, cannot be viewed without reverence ; and they will be available to the view of those who visit Down in future, for they go back there, together with the manuscript of the "Diary", which, as is well known, was published verbatim not many years ago under the care of Lady Barlow. The classified scientific notes, however, are rightly included in the Cambridge collection.

Letters are many. These have, of course, been exhaustively worked upon during the compilation of the "Life and Letters of Charles Darwin" and of "More Letters of Charles Darwin" ; nevertheless, they again are more appropriate to a library than to exhibition, and the majority go to Cambridge, though those written from the *Beagle* are retained for Down House with the notebooks. It has been noticed that such few letters as in normal times are open to view (in stands) in the Down House collection are assiduously read by many visitors ; but correspondence could never be exhibited in bulk.

There are a few scientific notes relating to Down and its neighbourhood, and these now return to their source. There is, for example, a list of plants, grasses, etc., on the lawn at Down, in 1856–58 : it might be a labour of love for a botanist to determine which of these, and how many more, appear there now. Among other local observations, there are the notes which were kept by Horace Darwin, from 1878 onward, in continuation of his father's study of the work of earthworms. Rainfall records are associated with the dampness and dryness of the soil, and these with measurements of the movement of the heavy stone (still in its place) which has become known as the wormstone : the term 'wormograph', which heads the notes, was mercifully relinquished.

Apart from the material already mentioned, the bulk of the gift to the British Association is not of a scientific character, but intimate and personal to Darwin, as befits a gift to the present guardians of his home. His own diary of his health, from 1849 to 1854, survives. A number of private account-books have been preserved. It is on record that Darwin rated his own business ability highly (if that phrase be not inapplicable to a man so innately modest) ; the account-books bear out this estimate. Personal expenditure is meticulously classified under various general headings—his partiality for snuff, by the way, is exhibited under the heading of "Amusements", and that of Mrs. Darwin for the theatre is apparent before they left London to live at Down. No less apparent is their generosity to dependants and others. Much may be inferred from these accounts concerning the regime at Down : the items of expenditure on the estate are not without value for the guidance of those who now are charged with its maintenance ; and the entries, in earlier days, concerning livestock and so forth do something to justify the surprising reference which occurs in Bagshaw's Directory of 1847—"Darwin, Charles, farmer".

EFFECTS OF CLOTHING AND FUEL SHORTAGE ON HEALTH*

By Sir Leonard Hill, F.R.S.

HAIR, feathers, fur and clothes protect the body from loss of heat, not by the quality of solid substance but by the air entangled in the meshes of these. Air is a bad heat conductor; warmed up to skin temperature and kept stationary, it acts as an insulator, preventing heat loss.

If the thermal conductivity of air be taken as unity that of wool fibre is 6, of water at least 240. The heat capacity of water is more than 3,000 times that of air, hence the great cooling power of cold water. A given volume of fur consists of about 2 per cent solid and 98 per cent air. A rabbit with skin shaved and varnished had its heat loss increased by nearly 1½ times in a room at ordinary temperature.

Darwin described natives of Tierra del Fuego—the woman with babe at her breast, naked in the falling sleet, the man with an otter-skin the size of a handkerchief, which he shifted to the side struck by the wind. Sleeping on the ground like hares these natives had to commit infanticide, so hardy were they, to keep the population down to the food supply. Native Australians kept dogs to warm themselves at night, stripping bark off a tree to protect their naked bodies from wind. Eskimo dressed in furs withstand howling blizzards and temperatures as low as 70° F. of frost, and will crouch with their spears over the holes patiently waiting for seals to come up to breathe, and so stay even for three days. In their igloos, built of snow blocks over ice, which is much warmer than frozen land, they use blubber-lamps, and are so warm with these and their own body heat, that they discard all clothing while inside. Roman Catholic priests, born in Paris, have acclimatized themselves to live as Eskimos protected by fur garments. One such priest lived in a hole in the ground, far colder than an igloo. The northern Chinese, who endure five months of rigorously cold weather, use little fuel, but attain comparative comfort by wearing a wadded gown with long sleeves, and wadded trousers bound round the ankle. Cotton waste is used as wadding. Contrast these garments with the thin underclothing, short skirts, silk stockings and thin shoes of our womenfolk. Here is the way to save fuel—if people wear suitable clothing, houses and factories need be far less heated. The Chinese do not have an open fireplace with most of the heat going up the chimney, but a stove, with a long metal pipe as flue, which, while traversing the room, gives up its heat.

To save fuel women's thin and flimsy garments can be amplified by overalls, trousers and tunics, with such undergarments as are available. Shawls, overcoats and mackintoshes can be worn indoors for sedentary occupations, and their protective effect can be amplified, if needed, by a hot bottle to the feet and a rug over the knees. People can thus keep warm without artificial heat, as they do in the back seat of a motor-car. The factories would then have to be artificially heated only just enough to keep the hands warm for skilled work.

For sedentary occupations an ordinary citizen secures an atmosphere under his clothes of about 91° F.; only about one fifth of his skin surface is exposed to the air. Naked he finds a room at 80° F. pleasant, one at 60° F. cold. Those who habitually go with little clothing and are most exposed to the open air show the greatest immunity to what are termed 'colds'—respiratory affections which are really caused by infection in stuffy, artificially heated rooms. Leaving aside the question of fuel-saving, modern girls in their scant attire get the advantage of sun and air, as does the boy scout with shorts, bare knees and a shirt open at the neck. Babies, for fear of cold, are often overclad, and head sweating and evaporation from the lungs are then sometimes the only means left for getting rid of body heat. The children in an open-air sanatorium, clad in one garment, sit up in bed and play, indifferent to open windows. Out of doors they enjoy exposure nude to sun and air, but the exposure must not be overdone. The children must be able to assimulate enough well-chosen food to produce the body heat production required.

Exposure to cold makes the lamp of life burn brightly. A baby is born with great powers to withstand changes of climatic environment. Well fed, and given some exposure to open air and sun, naked when the weather is good, allowed plenty of kicking and crawling, with no prolonged confinement when awake in cradle and perambulator, with long sleeps out of doors, and light clothing, babies grow up virile with strong muscles and firm bones. While in winter a man may carry a tenth of his weight in his clothes, a dog carries only 2 per cent of its weight in its fur. A woman in modern dress carries less than half as much as a man, but have in consequence suffered no more from 'colds', pneumonia or rheumatism, and their death-rate has not been put up. The secondary schools have turned out fine, healthy and athletic girls and the women have worked wonders in the munitions factories.

Clothing should not be so heavy as to interfere with the taking of vigorous exercise. The athlete wears scanty clothing because his efforts may increase his heat production by five times or more.

It is a mistake except in very cold weather to put on an overcoat when going out to walk. The overcoat is useful when sitting indoors so as to allow a window open on a cool day. It is only the old, the underfed and ill and feeble who require very warm clothing. It should be kept in mind that those who are paralysed, anæsthetized or in a state of shock have lost their power of heat regulation and may easily be over-heated by hot bottles and too much clothing. The difference between the winter and summer pelts of the horse and cow show the small amount of extra clothing needed to face the open air in winter. Thick woollens and furs are needed not by citizens but by arctic travellers, airmen and soldiers in freezing trenches.

Clothes require to be made so as to be easily adjusted to changes of climate, in place of being fashioned to satisfy vanity. They should be as light as possible, allow free evaporation, become to the least degree wet with sweat and not cling to the skin when wet. The cellular structure produced by weaving, whether of wool, cotton, linen or silk, secures conditions which by entanglement of air gives warmth, pliability and evaporative power. Smooth, closely woven and glazed materials, as in a mackintosh or oilskin, give protection from wind and water. Wool has an elastic fibre which when worn keeps the garment off the skin, and prevents it clinging when wet. A fine woven linen or cotton is cooler than flannel because less air is entangled within the meshes. Made equally cellular in structure, linen or cotton garments are as warm as flannel, but they cling when wet.

---

* Substance of a Chadwick Public Lecture delivered on October 6.

The question of wetting and clinging and of wearing and washing properties have to be taken into account. By taking off an outer garment, and by free ventilation, work can be carried out in factories in warm weather and without excessive call on the workers' sweat mechanism, which is the emergency method of keeping cool.

Fashion and custom should not prevent people taking off outer garments when feeling too warm. Employees should then be encouraged to work in their shirt sleeves, or bare to the waist. Heat loss from the body is then made easier by ventilation and free evaporation of sweat and by radiation of the skin to cooler surroundings. The evolution of the warm-blooded animal took place when animals warmed up by the sun succeeded by greater activity so induced, and came to evolve mechanisms for lessening heat loss in the shade by increasing heat production. Tropical lizards expand their pigment cells in their skin, and, absorbing sun rays, are warmed up to about 100° F. and then become very active. By open mouth and rapid breathing they evaporate enough water to prevent over-heating. At night they become cold and inert. Such lizards warmed by hot water pipes at the Zoo died in the winter. Given radiant heat on my suggestion, they eat and thrive. At body temperature black skin emits radiant heat rays just as much as white skin, but white skin reflects sun rays about double as much as black, which also absorbs much more. In the black and white furred animals exposed to the sun the black patches are much warmer than the white; so too, in the sun the dark hair of the scalp is much warmer than the white skin, but custom prevents consciousness of this difference. The sun's rays absorbed by the pigment of the skin increase transpiration from the capillaries and excite sweating and so cooling by evaporation. The black skin of a Negro when glistening with sweat reflects sun rays. Owing to protective pigment his skin can be thin and he blood vessels near to the surface; so the Negro loses heat easily from shaded parts of his body. The horny layer of the skin absorbs the short, active ultra-violet rays, and its thickening through exposure o these protects from sunburn. The pigment produced in the white skin by exposure to the sun protects the deeper parts of the skin from overheating.

Convention keeps children clothed in the tropics when they should wear only a loin-cloth, tan in the sun, be in and out of water and live open-air lives. Indoor conditions in the tropics make white women fade and age quickly. The white man can acclimatize himself to work in tropical heat when not overclothed and overfed. The conditions which favour heat-stroke are tight clothing and hot ground, high ir humidity, little wind and crowding. The limits of heat regulation in still air are wet bulb temperatures of 0° F. and 93° F. in air moving at two miles an hour; but work is then very inefficient. It is then most mportant to secure proper cooling of the body for workers by suitable clothing and ventilation. The heat loss from the body of a man engaged in ordinary physical work is required to be about three times that at rest, to counteract the greater body heat roduction.

The absorption of heat from the sun or a furnace may be much greater than the ordinary rate of heat ss, particularly in the case of a man in a black or dark garment. The conditions liable to give heatstroke are given by soldiers marching in full uniform, in close column in the sun on a calm day. Open order, stripping off of clothes, adequate water to drink, frequent rest, and a light diet are the means of prevention. White garments and helmets, and tents, reflect most sunlight, and the garments need to be open and flapping, so that ventilation is free. Shorts open at the knees, shirts open and short in the arms, and low cut and open in the neck are needed for hot climates. Aluminium foil can be used as a lining for tents to reflect sun-rays. Black or dark garments are worn in cold climates to absorb heat rays.

The cooling power of wind is enormous when the temperature is low. To resist this flying or arctic clothing consists of an outer layer of windproof material—strong, light, waterproof cloth will do—with inner layers of soft, fluffy woollens, entangling plenty of air. The garments join and even overlap, so that no wind enters at the neck, wrist, waist or ankle: a tunic with hood in one piece, gloves pulling up well over cuffs, and confined by straps, trousers coming well over tunic and confined by a belt, long boots made of supple hide coming well over trouser legs and strapped there, with soft woollen socks inside. A great trouble to arctic travellers is the moisture taken up by their sleeping-bags, which freezes by day and has to be thawed by night. Boots are best taken into the sleeping-bag to prevent them freezing. Wolverine is the fur used by Eskimos for head-cover because it does not take up the moisture breathed out.

Misty, damp atmosphere feels chilly owing to the hygroscopic properties of clothes and consequent dampness, with increased loss of body heat by evaporation of this moisture, while there is absence of radiant heat. Radiant heat from the sun and bright sky and warm ground or wall, make a great difference to comfort.

When bone dry, flannel will take up about 40 per cent of its weight of water, dry cotton or silk about half as much as wool; the physical process of the absorption of water by dry materials raises their temperature. For example, three layers of wool wrapped round the bulb of a thermometer were made quite dry in a drying-chamber. The thermometer rose 10° F. above the room temperature when it was suspended in the room owing to moisture absorbed from the air. Hence the warm feeling when well-dried clothes are put on. A woven cellular material takes up a great deal of water when wet, thus the clothing of a soldier may take up 8–9 lb. of water. To evaporate this amount would take up all the day's heat production of a sedentary worker. Woollens, owing to their elastic fibres, stick least to the skin when wet, and air still entangled in the meshes gives some protection against heat loss. Flannel is made up of 90 per cent air by volume and 2 per cent solid; smooth materials contain about 50 per cent of air. Starching and glazing make a garment almost airless, but impermeable to wind. Thus the smooth lining of an overcoat halves its permeability by wind.

While tropical clothing has a thickness of about 2 mm., winter clothing may be 12 mm. thick. The heat-retaining efficiency of clothing materials can be evaluated by means of the katathermometer. This, like the skin, is very sensitive to the cooling effect of wind. The ordinary thermometer gives the average temperature of the surroundings and is not affected by air movement. A room is comfortable when the 'kata' cooling power is 5–6. With the 'kata' clothed in a thick woollen glove the cooling power is about half what it is with the naked 'kata'. Where the so-clothed 'kata' gave readings of 3–5 and the naked 'kata' 6–10 on sunny days one can sit out in comfort in ordinary clothes. When in very cold weather the clothed 'kata' gave a cooling power of about 20, and the naked 'kata' about double as much, two overcoats, thick gloves and a muffler were needed, and even then one had to shelter from the wind to keep warm. If a rubber glove is pulled tight over the bulb of the 'kata' it gives almost no protection, but put on loose with fluffy wool underneath the protection is very great. When gloves of knitted wool, cotton, etc., are compared on the 'kata' it is evident that the nature of the fibres makes little difference. It is the air stationary in the meshes which protects. Three knitted garments put on the 'kata' bring down the cooling power to about one-third of that of the naked 'kata'. If the outermost garment be wet the protection is lessened only a little, as the cooling by evaporation from this coat is small. If a single, wet, thin, knitted glove clings to the 'kata' the rate of cooling is very greatly increased owing to evaporation. The 'kata' then becomes a measure of cooling power by convection, radiation and evaporation.

The cooling power of a wet 'kata' placed between the shirt and the skin is about trebled when a table fan is directed to blow on the body. The effect of such a fan in cooling the skin by convection and evaporation of sweat is thus made evident. The 'kata' does not actually give the cooling power exerted on the body, because it is a small bulb with a big surface in proportion to the bulk and surface of the large human body. The 'kata' cooling powers for comfort are then determined empirically. The cooling power exerted by water on the 'kata' is fourteen times that of air at the same temperature. Stirring the water makes the rate of cooling much greater. If a thick woollen glove be loosely put on and covered with a thin rubber glove, and this tied on to the stem so that no water can enter, the two coats protect the 'kata' from cooling in cold water very greatly, for example, they make it one seventh of that of the naked 'kata'. The protection becomes much less when the inner woollen glove is wet, but is still considerable. The clothes are then a protection against heat loss when one is immersed in water owing to the air entangled in the meshes, and the retention of water therein which becomes warmed by the body.

Swimming naked in the cold sea puts up the heat production of an ordinary man seven or eight times. Channel swimmers are protected by a thick layer of subcutaneous fat, which acts as an insulator, and their skin is well greased so that water cannot soak into it and increase its conductivity. Their heat production is very great owing to the powerful exercise as well as the cooling effect of water. They use up, therefore, some pounds of body fat and make this up afterwards. The heat loss of a naked man in air of 40° F. and a wind of 6½ ft. a second was found to be twice as great as when clothed. Exposed in boats or on rafts people want warm clothing and water or windproof outer garments to keep themselves from dying of cold. Such garments and enough water to drink are the two main essentials, as people when kept warm can live many days without food.

Dr. Argyll Campbell and I made observations on the rate of heat loss from the body of a subject exposed to wind and splashing of waves, either naked or in light clothing, or in such clothing plus a one-piece waterproof suit. This was made by Sir Robert Davis, of Messrs. Siebe Gorman, Ltd. The protection afforded by this suit was great, reducing the heat loss by one half. I directed the attention of the Minister of Transport to these observations, with the result that the Ministry designed a two-piece suit with a hood, all made of thin, light, oilskin material. The dress packs up in the hood, and this is carried by the merchant seamen just as a gas-mask is carried. More than 200,000 of these dresses have been issued, and the use of these contributes to the saving of life. The suit is coloured bright yellow, a colour easily seen from an aeroplane.

NATIONAL FLOUR AND BREAD

SECOND REPORT

From the Scientific Adviser's Division, Ministry of Food

SAMPLES of National flour and bread are being examined as a routine. The first report[1] covering 303 samples, of which 300 were received before 85 per cent flour became compulsory (March 23, 1942), showed that the mean values of fibre and B_1 were 0·70 per cent and 1·05 I.U./gm. respectively. The present report is a summary of the results obtained on 322 samples milled since the compulsory date together with a comparison of the quality of the flour before and after that date; it also summarizes the quality of 459 samples of bread.

Fibre and B_1. Table 1 shows the different levels of fibre and B_1 over the whole 322 samples:

TABLE 1

Fibre		Vitamin B_1	
Value %	% of samples	Value %	% of samples
⩽ 0·4	8·7	⩾ 1·10	46·6
0·5	13·7	1·00	80·7
0·6	29·8	0·90	93·5
0·7	50·6		
0·8	70·8		
0·9	85·1		

Since 85 per cent flour was made compulsory in Great Britain, millers have on occasions been allowed to admix a small amount of Canadian G.R. flour. In the period under review the average dilution in the samples received was 8·7 per cent. This would not affect the B_1 value, since the added G.R. flour is fortified to nearly the same level as National flour, but it would tend to reduce the fibre content; at a figure in the region of 0·7 per cent this reduction would be slightly less than 0·05 per cent. To compensate for this al the experimentally determined values of fibre have been increased by 0·05, although this correction, as an overall figure, is too great.

Riboflavin. Six flours taken at random from those having a fibre content of 0·7 per cent were examined for riboflavin[2], with the results shown in the second column of Table 2.

TABLE 2

Sample	Riboflavin γ/gm.	B_1 I.U./gm.	Germ content (approx.)
			%
1	1·7	1·00	1·0
2	1·9	1·10	2·0
3	1·7	1·15	1·0
4	1·7	1·20	1·8
5	1·3	1·00	1·2
6	1·7	1·15	1·0
Average	1·7	1·10	

Germ Content. In the absence of any satisfactory chemical method for estimating germ, estimates have been made based on the microscopic appearance of the flours when compared with standard preparations. The final column in Table 2 shows the results obtained with the six flours: a thorough examination was also made of twenty other flours of varying fibre content and taken at random. The same general result was obtained, the range of germ content being 1–2 per cent, with an average of 1·5 per cent. It should, however, be remembered that it is not the quantity but the quality of the germ that matters, and recent work has indicated that the dry milling of National flour will tend to retain the scutellum or vitamin B_1-rich fraction of the germ[3].

Granularity. There is no official specification for this aspect of National flour, but the Medical Research Council has advised (June 2, 1942) that all coarse bran (particles greater than 0·5 mm. cross-section) should be excluded, while the remaining particles should not have a cross-section greater than 0·2 mm. In practice this means that all the flour should at least go through a No. 5 silk. To some extent the ideal of a low fibre content and fine particle size run counter to one another, since in obtaining the maximum amount of endosperm (and least fibre) it s essential not to chop up the bran too finely. Progress, however, is being made, and the following gives a comparison of the average values obtained from he same hundred mills on samples (*A*) before, and amples (*B*) after March 23, 1942. In the case of amples (*B*) correction was made for the added G.R. flour, which was assumed to pass through a No. 10 silk.

	A	*B*
Over 32 g.g. (aperture 0·60 mm.)	3·5%	1·2%
Through 32 g.g. and over 5 silk	7·7%	6·4%
Total over 5 silk (aperture 0·27 mm.)	11·2%	7·6%

The improvement is also evident from the following figures, which show the average percentage fractions, for each successive 100 samples received, over No. 5 flour silk and No. 8 silk (aperture 0·19 mm.) respectively:

Sample No.	% over 5 silk	% over 8 silk
1–100	11·9	15·0
101–200	10·5	14·9
201–300	9·3	14·2
301–400	8·4	13·0
401–500	5·5	9·9

Comparison with Quality of Samples before March 23, 942. There are indications that the National average bre figure is decreasing and that the range of variation is becoming narrower. In order to attempt a comparison those mills which sent in samples before A) and after (*B*) March 23 have been included in a able in which each mill has been weighted on its milling capacity (sacks of flour per hour). In all, 49 mills have been included, and the following figures have been calculated for fibre:

Limit of fibre	*A* %	*B* %
≮ 0·50	10·8	26·3
0·60	30·2	46·7
0·70	56·3	75·5
0·80	79·7	86·5
0·90	92·6	90·5
1·00	96·0	99·3

A number of millers, realizing that commercial bran as such contains a considerable amount of attached endosperm, have adjusted their milling methods so as to scrape off this endosperm without chopping up the bran in the process. In this way they have been able, after prolonged experiment, to produce an 85 per cent meal with a fibre of 0·35–0·40 per cent. This technique is being followed in other mills but a limit will be set by the need for extra machinery. The following are typical samples:

	Sample 1 %	Sample 2 %
Over 5 silk	0·0	0·4
Over 8 silk	1·5	2·2
Over 10 silk	9·3	5·8
Fibre %	0·4	0·35
B_1 I.U./gm.	1·00	1·15

Quality of Bread

Four hundred and fifty-nine samples of bread have been examined. In every case a sample of the wheatmeal used was available in order to make any necessary check. The loaves were judged for quality by Dr. P. Halton and Mr. W. E. Spencer, and the following points taken into consideration: (1) general outside appearance; (2) volume; (3) crumb quality; (4) colour. Particular stress was laid on crumb quality, the standard being that of a first-quality commercial loaf. Four classes of quality were recognized—good, fair–good, fair and poor—and the following figures obtained:

Good = 278 loaves = 60·6%
Fair–good = 102 ,, = 22·2%
Fair = 58 ,, = 12·6%
Poor = 21 ,, = 4·6%

The chief defect was lack of proper fermentation and/or insufficient baking, giving a weak crumb.

The experimental work in this survey was carried out in the Laboratories of the Research Association of British Flour-Millers, St. Albans.

MINERAL RESOURCES OF THE U.S.S.R.*

By DR. DAVID WILLIAMS

SINCE the inception of the first Five-Year Plan in 1927 the U.S.S.R. has made great strides towards the goal of domestic self-sufficiency in mineral supplies. Under the ægis of central authorities such as the Institute of Geology and Prospecting and the Academy of Science, thousands of geologists have been engaged in the search for new resources, playing an essential part in the industrial revolution which has swept through the Soviet Union. Although vast areas still remain to be explored, probably no country is more nearly self-supporting, and certainly none has brighter prospects of industrial and agricultural expansion in times of world peace. To some extent this favourable position is due to methods of national economy, whereby commercial considerations are subjugated to national expediency.

* Paper read on July 25 at the Conference on Mineral Resources and the Atlantic Charter, arranged by the Division for the Social and International Relations of Science of the British Association.

The most important deposits of metallic minerals lie within the ancient and deeply eroded mountain chain which extends along the Urals and then swings eastwards through Kazakhstan into Central Asia, and to a lesser extent among the younger and more rugged mountains of the Caucasus and Eastern Siberia. In the gently undulating country of the Russian platform, to the west of the Urals, enormous deposits of potassium salts and phosphate rock ensure the Union a foremost rank in the production of mineral fertilizers.

Russia's immense reserves of coal, iron and petroleum afford a sure basis for industrial progress, and in each of these three most important commodities she is capable of long maintaining a surplus output.

Iron and Ferro-Alloys

Even omitting the astronomical tonnages of comparatively low-grade quartzitic iron ores of the Kursk district, the Soviet reserves of iron ore have recently been estimated at more than 10,000 million tons, surpassing those of the United States. In 1940 Russia produced 28 million tons of ore, about two thirds of which was raised from the Ukraine deposits of Krivoy Rog and the remainder largely from Magnitogorsk and elsewhere in the Urals. Among other extensive deposits are the oolitic, brown iron ores of the Kerch Peninsula in the Crimea, the magnetites of the Kuznetsk region, and the hæmatites of Far Eastern Siberia. With such huge resources of iron ore it is clear that the Soviet Union has the opportunity not only of fulfilling her own internal demands, but also of contributing a generous export supply.

Among the ferro-alloys Russia has been, within recent years, the world's largest producer of manganese and chromite, supplying respectively about a half and a quarter of the total world output. In 1936 manganese resources were computed at more than 700 million tons, sufficient for more than 200 years output at recent levels, the chief ore bodies being the two famous deposits of Nikopol in the Ukraine, and Chiaturi in the Caucasus. Although the output of chromite has increased during the past decade, it has latterly been used almost wholly for domestic requirements of ferrochromium and chromium chemicals. The principal mines lie near Sverdlovsk in the Central Urals. Unless fresh discoveries are made, Russia may feel compelled to retain her entire production of chromite for home consumption.

Russian supplies of nickel have so far proved to be inadequate, but by exploiting several extensive low-grade nickel silicate deposits in the Urals and nickel sulphide bodies in the Kola Peninsula and in Northern Siberia, she may well become independent of imports in times of peace. According to present information, however, it is unlikely that the U.S.S.R. will ever raise a surplus supply of nickel.

For tungsten and molybdenum the Union relies very largely upon imports. Both metals occur in widely separated localities throughout European and Asiatic Russia, many promising discoveries having been reported. Workable deposits of tungsten ore (wolfram) have been located in the Transbaikal area, but no great reserves are claimed. Much is expected from the new tungsten-molybdenum concentrator at Tyrny-Aus in the heart of the Caucasus, and from other mills erected for the recovery of molybdenum in Kazakhstan and Eastern Siberia. It seems reasonable to infer that the U.S.S.R. will eventually become self-sufficient in molybdenum, though the outlook for tungsten appears to be less promising.

Non-Ferrous Metals

Russia has for long held either first or second place among the world's platinum producers, and although full statistics have not been available lately, it is obvious that she will continue to be a foremost exporter of the metal. Until a few years ago, mercury was mined only at Nikitovka in the Donetz basin, but quicksilver deposits have now been opened u in the Kirghiz, and apparently the Union's mercury supplies and demands are roughly balanced.

Aluminium was first produced by the Soviets on a industrial scale in 1932, and although productio failed to reach the projected output the amount o metal won from bauxite had risen to 55,000 tons i 1940. The hope that a total production of 200,00 tons of aluminium would be attained in 1942 canno materialize, for some of the chief hydro-electric plants (Dnieper, Volkhov near Leningrad, Kandalaksha i Karelia) are now in, or close to, enemy hands In favourable circumstances, there are good prospects of achieving and even exceeding this figure though the discernible output for some considerabl time to come will be required for domestic use Bauxite reserves, sufficient for several decades, ar estimated at 45 million tons, the largest and riches deposits lying in the Urals to the north of Sverdlovsk Immense quantities of nepheline and alunite are als available for the production of alumina and aluminium, and already plants have been erected for treating nepheline tailings from the apatite works a Kirovsk in the Kola Peninsula. The potential suppl of nepheline, which contains about 33 per cent o alumina, must exceed 100 million tons.

Although Russia produced more than 100,000 ton of copper in 1938, she also had to import approximately two thirds as much. Most of the coppe smelted hitherto has been won from Uralian deposit (notably Degtiarsk, near Sverdlovsk) but the greates ore reserves are in Central Asia, at Kounrad an Djhezkazgan near Lake Balkhash, and at Almaly in the Tashkent area. The estimated resource of copper (metal) have been placed at 16 millio tons, and although this may be an optimisti figure, it is clear that when the mines and smelte are working to full capacity there will be no nee for the Union to import any copper from abroa

Production of lead and zinc has been steadil increasing during the past twenty years. Althoug the position with regard to lead is not yet satisfactory, the zinc output is probably ample fo domestic needs. During the three years precedin the outbreak of war the imports of lead and zin averaged approximately 30 and 2 per cent respectivel of the country's total requirements of those metal Russian reserves of lead and zinc have been ca culated at 11 per cent and 19 per cent respectively the world totals, the chief deposits and refineri being in the Caucasus (Sadon) and in the Alt Mountains of Kazakhstan (Ridder, Chimkent, Sol olny, and Belousovsk). In view of the likely futu demands, there appears to be small likelihood of th Union producing a surplus of these two base metal

Up to 1937, Russia was almost wholly dependen upon imports for both tin and antimony, receivin annually about 12,500 tons of the former and mo than 2,000 tons of the latter. Apparently the mo promising of the tin-bearing areas so far prospected lies in Eastern Transbaikal, but the recorded tonnages of proved ore are not large. Reports suggest that tin smelters may soon be operating in Yakutia and Tetiukhe, in Eastern Siberia. Unless tin substitutes are developed, however, it is inferred that the U.S.S.R. must continue to rely partly on imports of the metal. Valuable deposits of antimony ore have been discovered at Kadam Djai in the Kirghiz and in Central Siberia, and it seems justifiable to expect that Russia will be able to meet her own moderate peace-time needs of antimony.

Statistics for gold production are a State secret, but it is certain that the Union has adequate resources of this precious and enigmatic metal.

Non-Metallic Minerals

Russia's position with regard to many non-metallic minerals is stronger than that of any other country.

In recent years the U.S.S.R. has been the world's largest producer of crude magnesite. The Satka deposit, near Cheliabinsk in the Central Urals, alone yielded more than 800,000 tons of the mineral in 1937; including nearby deposits, the reserves are reputed to be about 250 million tons. Hitherto most of the output has been utilized for refractory purposes, but some magnesium metal is also manufactured from Satka ore. Although the production of metallic magnesium was less than 4 per cent of the world total n 1940, the potential output is enormous, for there are extensive supplies of raw materials from which the metal can be extracted, notably the rich carnallite $KMgCl_3.6H_2O$) deposits of Solikamsk in the Western Urals, brine from various salt lakes, and the Satka magnesites.

Russian geologists claim that the prospected phosphate rock deposits of the U.S.S.R. now exceed 60 per cent of the world's resources. Near Kirovsk, in the Kola Peninsula, remarkable bodies of apatite, discovered in 1926, have recently been yielding more than 2 million tons of ore annually, with reserves for another millennium. The principal phosphorite deposits occur in European Russia, in the regions of Kirov (Phosphoritnaya) and Moscow (Egorjevsk), but an extensive and favourably situated field near Aktiubinsk in North-west Kazakhstan is being developed to supply agricultural fertilizers for western Soviet Asia.

No details of mica production have been issued since 1935, when the Union held second place in world rank. The muscovite pegmatites of the Mama-Vitim area in Eastern Siberia and the Chupa Fjord district of Karelia, and the phlogopite veins of Slyudyanka at the western end of Lake Baikal, are doubtless capable of providing adequate supplies for domestic consumption. For many years the Russian output and export of asbestos has only been exceeded by that of Canada. The yearly production of chrysotile asbestos from the well-known Bazhenov field, near Sverdlovsk, is roughly 100,000 tons, the total reserves amounting to more than 30 million ons. It is unquestionably one of the largest and most productive asbestos fields in the world.

The region of Solikamsk, on the western slopes of he Urals, has long been known for its brines and alt works, but it was only after deep boring commenced in 1925 that the remarkable deposits of potassium and magnesium salts (sylvinite and carnallite) and the enormous masses of rock salt were horoughly investigated over an area of some 700 square miles. Production started in 1932 and within five years the annual output had risen to more than two million tons of crude salts, and large quantities were being exported. Solikamsk reserves are claimed to represent about 80 per cent of the world's resources, consisting of 15,000 million tons of potash salts, 18,000 million tons of magnesium salts, and scores of thousands of millions of tons of rock salt. Even the famous Stassfurt deposits of Germany are dwarfed.

In 1938 Russia was among the leading producers of pyrite, with a tonnage approaching one million, derived chiefly from the Uralian cupriferous bodies (especially Degtiarsk) and from various coal mines. Expeditions to the Kara Kum Desert and the Gourdak Range in Turkmen territory, east of the Caspian Sea, have discovered huge supplies of native sulphur, quite comparable with the great Sicilian deposits. These Turkmen occurrences are likely to be the main future supply of sulphur, except in areas where it is being recovered during the treatment of sulphide ores.

Adequate resources of other minerals, such as graphite, fluorite and gypsum, are known to exist within the Union.

The development of mineral resources in the U.S.S.R. during the past fifteen years has far surpassed anything formerly achieved in a like period of the world's history. Sceptics may doubt the validity of some of the Russian estimates of ore reserves, but it should be recalled that vast territories still await detailed investigation and that the actual resources might well prove to exceed those now claimed. Despite the present marked deficiency in a few metals, notably tin and tungsten, it is reasonable to suppose that the U.S.S.R. will eventually become almost entirely self-supporting and may be able to export large quantities of coal, iron, petroleum, manganese, platinum, magnesite, phosphates, asbestos, potash and sulphur. The U.S.S.R., with her immense natural resources and man-power, has much to offer in the cause of world progress and welfare, and not least a share in her abundant mineral wealth.

OBITUARIES

Prof. A. Ukhtomsky

THOSE physiologists from Great Britain who had the good fortune to attend the International Congress of Physiology at Leningrad and Moscow in 1935 will remember the picturesque figure of Prof. Ukhtomsky and his novel and philosophic approach to the problems of nervous physiology. As successor to Wedensky, he had done much to develop the ideas of his brilliant teacher. It is with great regret that we now learn of his recent death in a message from Prof. K. Kekcheev addressed to the Physiological Society, on which the following notes are based.

Alexey Ukhtomsky was born in 1875 and for twenty years held the chair of physiology in the University of Leningrad, to which he was appointed on the death of his teacher, the well-known Russian physiologist Wedensky.

Ukhtomsky is known for his numerous researches into the excitation inhibition of the central nervous system. In 1911 he established the principle of the 'dominant', according to which, given the presence of any excited point in the brain, other auxiliary excitations do not call forth the usual reflexes but serve to enhance the excitation of the given point.

One of the most clearly demonstrated examples of the dominant is the substantial enhancement of the embracing reflex in male frogs at a certain season of the year when any part of the skin is excited. Several of Ukhtomsky's researches were devoted to the time factor and 'system history' in phenomena occurring in nerve tissue during excitation inhibition.

In recent years, Ukhtomsky was interested in the physiology of labour, and his laboratory, under the direction of his collaborator Prof. M. Vinogradov, was one of the centres of this science in the U.S.S.R.

The work of Ukhtomsky and his school was published chiefly in the *Proceedings of the Physiological Institute of the University of Leningrad*, of which he was editor, and in *Educational Records of the University of Leningrad*.

Prof. K. N. Moss, O.B.E.

Prof. Kenneth Neville Moss, professor of coal and metal mining in the University of Birmingham since 1922, died on October 20 at the early age of fifty-one. Prof. Moss was very active and successful in the direction of the Mining Department of the University, and was mainly responsible for the raising of £100,000 for developments in the Faculty of Science, of which for four years he was dean. A notable scheme which he carried through was the institution of a number of scholarships to attract public-school boys to the Mining Department.

Prof. Moss was educated at Queen Mary's School, Walsall, and the University of Birmingham. He had practical experience of mining in the Cannock Chase, South Yorkshire and North Staffordshire coalfields and was for a year organizer of mining education for Derbyshire. Among other positions which he had held, he was chairman of the Advisory Committee on Coal and Petroleum of the Mineral Resources Department of the Imperial Institute, president of the National Association of Colliery Managers, president of the South Staffordshire and Warwickshire Institute of Mining Engineers, and a member of council of the Institute of Mining Engineers.

During the War of 1914–18, Prof. Moss was captain and adjutant to the 59th Divisional R.E., was awarded the O.B.E. (Military Division) and twice mentioned in dispatches. The loss of his forceful personality will be severely felt by the University of Birmingham. He leaves a widow and four daughters.

G. A. Shakespear.

We regret to announce the following deaths:

Prof. Alfred Baker, emeritus professor of mathematics in the University of Toronto, where he occupied the chair of mathematics from 1887 until 1919, who was president in 1915 of the Royal Society of Canada, on October 27, aged ninety-four.

Prof. J. N. Collie, F.R.S., emeritus professor of organic chemistry in the University of London, on November 1, aged eighty-three.

Prof. J. C. Schoute, emeritus professor of botany in the University of Groningen, president of the Sixth International Botanical Congress, aged sixty-five.

NEWS and VIEWS

Educational Biology

Eminently sane, though occasionally somewhat diffuse, are Mr. Hugh Ramage's views on "Educational Biology" (*Sch. Sci. Rev.*, No. 91; June, 1942). Emphasizing the key position of biology in any adequate scheme of education, he takes the unequivocal stand that educational biology should centre upon a study of the human organism. There are many biologists who refuse to accept this view, but the author cuts a good deal of the ground away from the feet of potential opponents by his recognition of the importance of studying organisms valuable in the illustration of principles. Mr. Ramage also trails his coat on the controversial topic of sex education, but he speaks very good sense, here as elsewhere. Very salutary is his endeavour to check the swing of the pendulum away from a mere study of cadaver, before it reaches the position of the unco-ordinated study of 'function' isolated from the organism that functions. Salutary, too, is his insistence on the need for attention in school to problems of variability and ecology. It is rather difficult to be certain from this paper whether the author's outlook is that of a holist or a dialectical materialist, and indeed the teleological implications of the statement that organisms form a "purposive" entity (albeit with inverted commas) give ground for suspicion that perhaps Mr. Ramage takes up no consistent philosophical position. But he poses clearly here many problems of educational method which should receive the attention of all teachers.

Engineering in Agriculture

In his presidential address to the Institution o Civil Engineers delivered on November 3, Sir John Thornycroft pointed out that his work has been so closely connected with the Navy, and to a smaller extent with the Army, that he considered it inadvisable in present circumstances to talk about it, as has usually been done by presidents of the Institution He has, however, taken a great personal interest in engineering in agriculture, and he devoted his address to that topic. From the earliest times the engineer has played a very important part in helping the agriculturist in irrigation, drainage, land reclamation and in the provision of implements which enable men, with the aid of oxen and horses, to do so much more than was possible with the primitive hoe and mattock. The address dealt in detail with the problems of land drainage, soil erosion, and the application of steam and internal-combustion engines to tractors and farming machinery—ploughs, machines for sowing seed in drills and for planting root crops and potatoes, and harvesting machines. The importance of research was emphasized and mention was made of the establishment by the Government of the Agricultural Machinery Development Board and o an Institute of Research in Agricultural Engineering A very large home-grown sugar industry has been built up in Great Britain in recent years, and the British Sugar Corporation has contracts with more than 52,000 farmers, who provide 400,000 acres o the crop; the whole of the domestic sugar ration allowed in Great Britain at present is home-grown. The application of electric power was discussed and its extension urged, with a suggestion that town dwellers and industrialists should be charged an overriding percentage so that supply companies would be able to distribute current to every agricultural holding at the low prices available to town dwellers.

Agriculture To-day and To-morrow

THE Royal Society of Arts has arranged a special series of ten lectures on "Agriculture Today and Tomorrow", beginning on November 11. In organizing these lectures, the Society is carrying on what was for nearly a century one of the most important branches of its activities. At the time of the Society's foundation—1754—the methods of agriculture were practically those of the Middle Ages. Until the inauguration of the Royal Agricultural Society in 1838, the Society's Committee of Agriculture under Arthur Young was the most important body in Great Britain concerned with the welfare of agriculture. Under its auspices many improvements were made in agricultural practices. The Society also opened to the public its "Repository of Inventions", which contained an excellent collection of models of agricultural implements, and in 1761 it held an exhibition of agricultural machines. Although the present lectures are intended mainly for those actively engaged in agriculture, it is emphasized that the series will be of interest to laymen. A syllabus of the series can be obtained from the Secretary, Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2.

Utilization of Rural Waste

FOLLOWING on the article by Mr. Bransby Williams on the manufacture of fertilizer from urban wastes (NATURE, Sept. 5, p. 299), it is interesting to note that an experiment in rural sanitation is being conducted by Dr. A. T. Westlake on his estate at Sandy Balls, near Fordingbridge. The estate is used as a holiday centre, and a large number of visitors, living in huts, caravans, and tents, pass through it in the course of the year, in addition to a resident population of about forty persons. The Poore method was at first tried, but later Dr. Westlake adopted the Indore composting system of Sir Albert Howard with good results. All the night soil and other refuse on the estate is composted in heaps. There is separation of solids and liquids. By the use of specially dried earth and leaf mould, the collection and handling of the material is rendered efficient, easy, and hygienic. In winter the method so far adopted has been the use of small composting pits. The matured compost is used to manure what was formerly barren ground, but which has now become a healthy and flourishing kitchen garden. Plant disease has been very largely eliminated. It is clear from the experiment that the methods used here might well be tried in other rural communities.

Engineering Cadetships

THE Government announces the foundation of engineering cadetships, open to youths of sixteen to nineteen years of age, inclusive, and leading to technical commissions in the fighting services. The Government will pay the necessary educational fees and allow each cadet a maintenance grant. Youths of 16–19 are invited to apply if (*a*) they left school before October of this year; (*b*) are not employed in any branch of engineering; and (*c*) have obtained at least the school certificate with a credit in mathematics or general science or physics or an equivalent examination. The length and character of the training, which will be at a technical college, will be adjusted to age and educational qualifications, and may extend to two and a half years. Boys of sixteen will have preliminary instruction at a technical college or other appropriate institution. The training courses will cover the basic engineering science required in the associate membership examinations of the Institution of Mechanical Engineers or the Institution of Electrical Engineers. In the case of the Institution of Mechanical Engineers, cadets who successfully complete their course will be exempted from sections A and B of the associate membership examination. Youths of eighteen who have been called up may apply for cadetships, and boys born in 1924 and still at school may also be accepted. Applications will be received by local appointments offices of the Ministry of Labour and National Service or by the Appointments Department, Sardinia House, London, W.C.2.

Russian-English Technical Glossaries

As a result of the appeal by Sir John Russell, chairman of the Anglo-Soviet Scientific Collaboration Committee, for Russian-English technical dictionaries, sixteen glossaries of Russian technical and scientific terms have been collected and placed in the Science Library, South Kensington, London, S.W.7, where they are available for consultation. Most of the glossaries, which cover a wide range of subjects—military and naval terms, metallurgy, medicine, botany, fuel technology and bacteriology of fish—have been compiled by individuals during the course of their work in a special field. Some are printed, others are typed or in duplicated form, while others are in manuscript or on cards. A list of these glossaries giving the name and address of the compiler or donor can be obtained from the Secretary of the Anglo-Soviet Scientific Collaboration Committee, British Council, 3 Hanover Street, W.1. A location list of Russian technical glossaries has also been compiled by the Anglo-Soviet Scientific Collaboration Committee. This list, which incorporates the glossaries collected for the Science Library, also indicates the libraries in which copies of the chief Russian scientific and technical dictionaries may be found. Copies of the location list may also be obtained upon application to the Secretary of the Anglo-Soviet Scientific Collaboration Committee.

Map of Europe and Middle East

A MAP of Europe and the Middle East on a scale of 1 : 11 million has been published by the Royal Geographical Society on behalf of the British Council. The map is drawn on Murdoch's third conical projection and extends from Western Europe, the British Isles and Iceland east to Rangoon and south to Abyssinia. It will fit obliquely with two adjoining sheets, North America to Britain and the Far East, which are now published in outline only but are to be completed later. Land relief is shown by contours and layer colouring in tints of brown and hill shading in lavender grey corresponding to a light thrown from the top left-hand corner of the plate. Contours are at 50, 100, 200, 500, 1,000 and subsequent 1,000 metres, which is fully as many as the scale can bear in some areas. Principal railways are shown as red lines and selected roads as red dotted lines. Political boundaries as in 1938 are marked and there are also shown oil fields, pipe lines, ancient sites, deserts, marshes and glaciers. No submarine relief is shown: water is blue. Names of countries and principal rivers and towns are in black. An edition with names in Arabic is to be published. The present sheet (No. 1), flat or folded, costs 5*s*., or, flat, with the outline edition of No. 2 and No. 3, which are not sold separately, 8*s*.

Sir Robert Kane

UNDER the auspices of the Chemical Society of University College, Cork, Mr. D. Ó. Raghallaigh has recently issued an interesting booklet of forty-three pages dealing with the life and work of Sir Robert Kane (1809–1890), a pioneer of chemistry and of industry in Ireland. Kane studied medicine at Trinity College, Dublin, and became professor of chemistry at the Irish Apothecaries' Hall at the age of twenty-two. After his appointment to the chair of natural philosophy at the Royal Dublin Society in 1834, he published his important work on ammoniacal compounds of mercury, copper and zinc. This was followed in 1840 by a research on the colouring matter of lichens, and soon afterwards Kane was elected F.R.S. His "Elements of Chemistry", completed in 1843, achieved fame as a standard text-book. He took far-sighted views of Irish industries and agriculture; for example, he directed attention to the chemical potentialities of Irish peat and potatoes, and depicted the Shannon Valley as the future industrial centre of Ireland. In organic chemistry he accomplished the first synthesis of a cyclic compound (mesitylene) from an open-chain one (acetone). In 1845 Kane became the first president of the new Queen's College, Cork, and in the following year he was knighted for his services to science and Irish industry. After his resignation of the presidency in 1873 he became first dean of the Royal College of Science for Ireland, and later he was appointed vice-chancellor of the Royal University. One of Kane's sons commanded H.M.S. *Calliope* in the historic escape of this ship from Samoa Harbour during the hurricane of March 15, 1889.

Wood-Pigeon Investigation

THE third Bulletin of the Wood-pigeon Investigation, issued by the Edward Grey Institute of the University of Oxford, covers some of the findings of the past nesting season, and the expansion of the investigation to have 500 observers recording 250 birds a month next breeding season, thus recording more than a million birds. In some parts of Great Britain during 1942 the birds were very sparse with only one or two nests in a hundred acres, and in others their nests were sufficiently concentrated to show definite breeding colonies with preference for certain areas. The most densely populated haunts were young spruce plantations. At the peak of the breeding season in August (it is much later than with most birds) these dense haunts had as many as twenty nests in four acres. At the end of September there were still 10–20 nests occupied in some plantations. Many districts had more occupied nests in July than in June.

It is hoped to gain a better knowledge of the distribution of the nesting colonies throughout Great Britain in order to understand how they came to exist. The life of a wood-pigeon is long, but it is desired to know how long and how it varies with different types of woodland. The breeding season of the wood-pigeon does not necessarily coincide with that of other woodland birds. The possible connexion between late breeding and the formation of colonies is to be investigated. In the winter countryside, as in the nesting season, the wood-pigeon population is not evenly distributed. The filling in of record cards of winter flocks can give their distribution month by month, as well as their autumn, winter and spring movements, and a seasonal guide to feeding-grounds and flock sizes, favourite feeding hours and the relative number of stock doves feeding in the flocks. A collection of photographs is also being built up of nests, crop damage, and 'colony' woods.

Biology of Oysters

THE oysters of Australia are being thoroughly investigated by the Division of Fisheries, Council for Scientific and Industrial Research. In the first of the series of pamphlets on the biology and cultivation of oysters in Australia, G. A. Kesteven wrote on some economic aspects (Pamphlet No. 105; 1941). A more recent publication, in two parts, is by G. Humphreys (2. A Note on the Calcium Content of Some East Australian Waters; 3. Biochemistry of the Proximal Constituents. Commonwealth of Australia. Council for Scientific and Industrial Research, Division of Fisheries. Report No. 7. Pamphlet 111. Melbourne, 1941). The calcium content of a number of oyster-growing waters has been investigated and the relation between condition and the fluctuation in the proximate constituents of the oyster, namely, carbohydrate fat and protein. It is concluded that there is no essential difference in calcium content between waters where oyster growth is normal and waters where only stunted growth appears. Opinions differ as to the role of glycogen in the oysters, some maintaining that it determines fatness, others that it is a reserve food material. The author shows that the latter view is correct, for the fattest oysters occur just before spawning when the glycogen percentage is at its minimum. The idea, supported by recent investigators, that glycogen is stored as a reserve food material and is used for the formation of gonad products which do not consist of glycogen is borne out by the figures presented, in which it is seen that for healthy oysters the glycogen percentage is in the range 3–7 during most of the year, but that just when the oysters are about to spawn, the value is below 2. It is found that oysters can be dried with no loss of glycogen or protein.

Impregnating Varnishes

W. J. KIERNAN points out in a recent article (*Bell Lab. Rec.*, **20**, No. 12; August 1942) that until the recent development of synthetic resins and drying oils the impregnants applied to coils contained linseed or china-wood oils and natural resins, and that they 'set' by surface oxidation, leaving the interior in a semi-fluid state. Fatty acids were usually present in the unset portion, sometimes in sufficient strength to corrode copper. Varnishes made with synthetic resins of the phenol-aldehyde type polymerize on drying rather than oxidize, and produce a solid state throughout their mass. Corrosive tendencies are negligible or entirely absent because of their complete setting and low acid content. When thoroughly dried by baking at high temperatures, they are no longer thermoplastic. This allows coils to operate at higher temperatures without softening the impregnating material and permits substantial savings by reducing the size of the coils. The penetrating power of these synthetic resins and their high dielectric strength make them particularly valuable for high-voltage circuits where corona discharges might occur and, by oxidizing the nitrogen, produce nitric acid which breaks down the coil insulation. Retardation coils and power transformers of several types, designed for telephone apparatus, are now being impregnated on a production basis with synthetic resin varnishes. The results indicate advantageous possibilities for their wider use.

Tuberculosis Control in Argentina

ACCORDING to Dr. Hugo J. D'Amato, secretary of the National Department of Health of Argentina (*Bol. Of. San. Panamer.*, 21, 772; 1942), family contacts have been examined in the last few years at the tuberculosis dispensaries of this department in order to discover unrecognized cases. As this procedure, however, did not include extra-familial contacts a new organization is being planned which will involve systematic and repeated examinations of the entire population. At present all public employees and all applicants for Government positions have to undergo clinical and radiological examinations of the thorax as well as tuberculin tests. Of 10,863 persons examined 104 were rejected and 51 were accepted with a temporary certificate while under treatment. Only six of the 10,708 applicants declared to be healthy or 60 per 100,000 have developed tuberculosis in the course of two years, whereas before examination was made compulsory the rate of infection was 520 per 100,000. In August 1941 the National Commission of Tuberculosis was created, which besides centralizing the administration of the tuberculosis control campaign, has power to propose measures regarding salaries, housing, nutrition and industrial hygiene.

Earthquakes Registered in Switzerland

DURING July and August 1942, thirty earthquakes were registered by the instruments at the Swiss observatories of Zurich, Chur, Basel and Neuchâtel (*Swiss Earthquake Bull.*, No. 146 and No. 147). The distant earthquakes have, for the most part, been mentioned previously in the columns of NATURE, but the local earthquakes have not. On July 1 an earthquake was felt with intensity V (Rossi-Forel scale) in the Pays d'Enhaut. It was registered at Zurich at 23h. 43m. 13·3s., the epicentre being some 135 km. distant. On July 17 an earthquake was registered at Chur at 10h. 27m. 08·8s., which had its epicentre in the Schwäbische Alb, and on July 18 an earthquake registered at Basel at 15h. 46m. 08·3s. had its epicentre less than 10 km. to the north-west of that station. The earthquake of August 27, registered at Zurich at 11h. 11m. 21·9s., had its epicentre 70 km. from that station and was felt in the neighbourhood of the Brünig and Lungernsee. Finally, the earthquake of August 28, registered at Zurich at 11h. 28m. 58·4s., had its epicentre 71 km. from that place and was felt with intensity V in the neighbourhood of the Hohenstollen.

An Important Binary Star System

DR. R. M. PETRIE, of the Dominion Astrophysical Observatory, Victoria, B.C., reports the discovery of another sub-dwarf star, a component of the binary system *HD* 144208–9 (*Sky and Telescope*, August). The primary in the system is of class *G* and the dwarf is of class *A* and a normal object for its class. Its luminosity in terms of the primary was determined from the combined spectrum of the two stars, in which the metallic lines and the *K* line of calcium are weaker than normal, and the wings of the Balmer hydrogen are stronger. The assumption that the primary obeys the mass-luminosity relation—mass proportional to absolute magnitude—made it possible to determine the masses and mean densities of both stars. Many other binary systems exist in which the components are *G*- and *A*-type, and the investigation of these systems is important that more may be understood about the relationship of the sub-dwarfs to the white dwarfs.

A Radiological Library

A RADIOLOGICAL library valued at £3,500 is on sale by the Museum Book Store, 45 Museum Street, W.C.1, by whom a 12-page pamphlet is issued. This world-wide collection of journals and periodical publications, each in the language of its origin, is not likely to be duplicated, and it is hoped that it will find its way into some research laboratory or radiological centre. The chief publishers of radiological subjects have been the United States, Germany, France and Great Britain, and we can think of no X-ray or radium journal which is not included in this library. This offer of sale has now been open for some months and the step of acquiring the valuable collection waits to be taken by some authority with vision as well as money.

Prof. F. H. Garner

THE chair of oil engineering and refining in the University of Birmingham, rendered vacant by the death of Prof. A. W. Nash, has been filled by the appointment of Dr. F. H. Garner, a graduate of the University (1914). Dr. Garner was for many years chief chemist of the Anglo-American Oil Co. and is that company's principal scientific officer in Great Britain; he has a high reputation and an excellent record as a research chemist in the field of oil chemistry. He has acted as an external examiner in the Oil Engineering Department of the University of Birmingham for several years and has thus a knowledge of the working of the Department.

Announcements

THE Emil von Behring prize, which is awarded by the University of Marburg every two years for outstanding achievements in immunology, serum therapy and chemotherapy, has been awarded to Prof. Paul Uhlenhuth, professor of hygiene and bacteriology in the University of Freiburg-im-Breisgau.

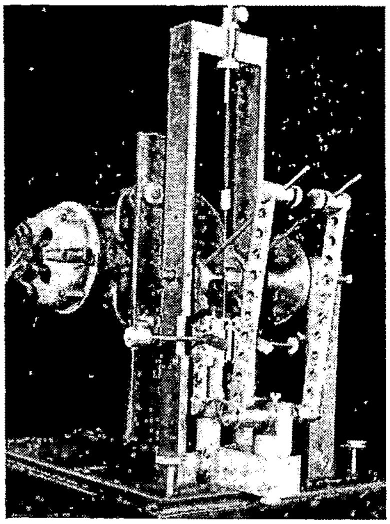
WE have received *Abstracts of Articles and Patents on the Production of Glycerol by Fermentation* published by the National Research Council of Canada, Ottawa, 1942, which contains abstracts of 109 articles and 114 patents on this subject. The publication is N.R.C., No. 1070, price 50 cents.

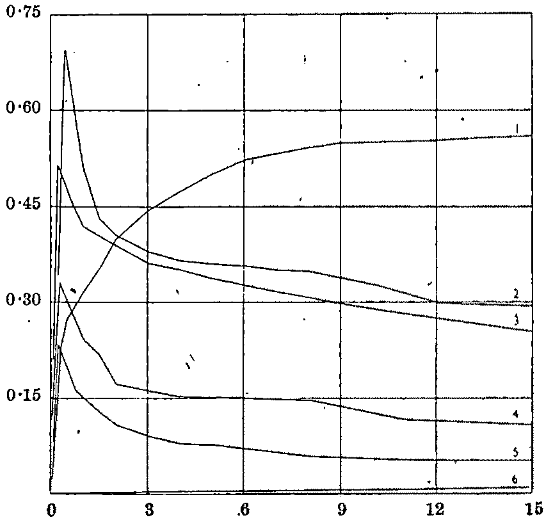
LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Scaliness of Animal Fibres

One of the most important properties of wool fibres is their ability to migrate in the direction of the root end when rubbed, especially in presence of a solution of soap or acid. With fabrics and masses of loose fibre, migration takes place in much the same way as a worm crawls[1], and is due primarily to the surface scale structure of the fibres. This peculiarity is turned to advantage in the manufacture of felts, and to meet an obvious need, a method of measuring the scaliness of different types of fibre was devised some years ago[2]. It consists in mounting fifty fibres in parallel, with the scales all pointing in one direction, and then measuring the frictional resistance to motion towards the root ends and towards the tips of the fibres. The observed difference in (static) friction in the two directions gives a measure of scaliness. Although the method has given useful results, it suffers from a number of defects. Besides being tedious in use, it gives no opportunity of studying the properties of individual fibres, and is not very closely related to the practice of felting, where dynamic friction is operative.





1, Human hair. 2, New Zealand Romney wool. 3, Lincoln wool. 4, Cotswold wool. 5, Mohair. 6. Kemp (from Blackface fleece).

To overcome these defects, a new method of measuring scaliness has been evolved. The apparatus is shown in the illustration. A single fibre, with the tip-end uppermost, is rubbed at a standard rate between two opposed, reciprocating, plane surfaces under controlled pressure, the surfaces being clothed with silk bolting-gauze or other suitable material. The fibre creeps downwards against a gradually increasing tension in the calibrated spring, to which its tip-end is attached. A measure of scaliness is given by the rate of increase of tension and by the maximum tension developed, allowance being made, if necessary, for variations in fibre diameter.

Typical curves showing the rate of development of tension with various fibres are reproduced. They reveal an interesting phenomenon. Whereas the maximum tension developed in the case of human hair is maintained over long periods of rubbing, the various wools examined show a rapid fall in tension as soon as the maximum has been attained. Besides possessing different degrees of scaliness, therefore, animal fibres clearly vary in their resistance to abrasion. Both factors, the second of which has hitherto been neglected, must play a part in determining the felting power of different wools, and their mode of operation under different conditions of humidity, temperature and pH is now being studied with the new apparatus.

Vitamin Requirement of the American Flour Beetle *Tribolium confusum* Duval

The larvæ of the American flour beetle *Tribolium confusum* Duval can only develop on a diet consisting of protein, carbohydrate, salts, and water if yeast or some other suitable vitamin source is added[1]. Fröbrich[2] found the addition of 5 per cent of dry yeast to a diet of casein, rice starch and Osborne-Mendel salt mixture in a relative humidity of 70–75 per cent to be sufficient. For the activity of the yeast extract thiamine, riboflavine, and an unknown factor B_x were important; in the insoluble fraction there were recognized as necessary ergosterol (which could be replaced completely by cholesterol) and a further unknown factor, U. Offhaus[3] obtained similar results with a diet of dried egg-white, rice starch, and di-potassium hydrogen phosphate, but found that the insoluble yeast fraction could be completely replaced by cholesterol + histidin. Fraenkel and Blewett[4] have also investigated this problem.

During the past two years we have carried out experiments with Tribolium larvæ, which have furnished somewhat different results. One-day-old larvæ in groups of five were kept at 34° in a relative

TABLE 1.

Diet: 1·5 gm. given	No. of animals observed	Results after 22 days			Growth response
		Larvæ	Pupæ + Adults	Dead	
(*a*) Wholemeal	5 5	– –	5 5	– –	Good
(*b*) Deficient diet	5 5	5 5	– –	– –	None
(*c*) Deficient diet + 75 mgm. dry yeast	5 5	– –	5 5	– –	Good
(*d*) Deficient diet + 37 mgm. insoluble yeast	5 5	5 5	– –	– –	None
(*e*) Deficient diet + 37 mgm. yeast extract	5 5	5 5	– –	– –	None
(*f*) Deficient diet + 37 mgm. insoluble yeast + 37 mgm. yeast extract	5 5	– –	5 5	– –	Good

humidity of 70–75 per cent on 1·5 gm. of a deficient diet, and the pupæ counted after 22 days. The deficient diet consisted of 20 per cent casein (vitamin-free), 75 per cent rice starch, and 5 per cent McCollum salt mixture. Dried brewer's yeast was boiled for 2 hours with 5 parts of distilled water, the treatment repeated nine times, and the insoluble fraction dried. The united aqueous extracts were largely evaporated *in vacuo*, alcohol added to give an alcohol content of 80 per cent, the precipitate removed, and the clear filtrate evaporated *in vacuo* and dried (yeast extract).

TABLE 2.

Diet: 1·5 gm. given	No. of animals observed	Results after 22 days			Growth response
		Larvæ	Pupæ + Adults	Dead	
(*a*) Wholemeal (control)	5 5	– –	5 5	– –	Good
(*b*) Deficient diet + 35 mgm. insoluble yeast + 10 addenda*	5 5	– –	5 5	– –	Good
(*c*) Deficient diet + 37 mgm. insoluble yeast + 3 addenda**	5 5	– –	5 5	– –	Good
(*d*) Deficient diet + 35 mgm. insoluble yeast + 2 vitamins*** + 0·25 γ biotin (pure)	5 5	– –	5 5	– –	Good
(*e*) Deficient diet + 35 mgm. insoluble yeast + 2 vitamins*** (without biotin)	5 5	5 5	– –	– –	None
(*f*) Deficient diet + 100 γ cholesterol + 3 addenda**	5 5	– –	5 4	– 1	Good
(*g*) Deficient diet + 100 γ cholesterol + 2 vitamins*** + 0·25 γ biotin (pure)	5	–	–	5	None

* 10 Addenda : 10 γ thiamine, 8 γ riboflavine, 10 γ pyridoxine, 5 γ calcium pantothenate, 500 γ nicotinic acid amide, 2 mgm. *meso*-inositol, 1 γ *p*-aminobenzoic acid, 10 mgm. SiO_2, 10 γ KI, 15 mgm. biotin preparation from liver (= 0·3 γ pure biotin).

** 3 Addenda : 10 γ thiamine, 500 γ nicotinic acid amide, 15 mgm. biotin preparation from liver (= 0·3 γ pure biotin).

*** 2 vitamins : 10 γ thiamine. 500 γ nicotinic acid amide.

The separation of the active constituents was complete (Table 1).

It was then found that the 37 mgm. of yeast extract could completely be replaced by a mixture* (Table 2, *b*) of the ten components of which only the biotin preparation was non-homogeneous. By omitting individual components it was shown that two pure vitamins**, namely, thiamine and nicotinic acid amide, together with 15 mgm. of a biotin preparation (= 0·3 γ biotin) were sufficient (*c*). The biotin preparation in this combination*** could be replaced by an equivalent quantity of pure biotin (*d*), the necessity of which was again demonstrated (*e*).

By using the three-component mixture** as the vitamin source, the insoluble yeast fraction could completely be replaced by 100 γ cholesterol (*f*); this could not be accomplished by use of the two crystalline vitamins*** with pure biotin (*g*). Thus the water-insoluble yeast fraction contains at least one other factor which is necessary for the development of Tribolium, and which is also present in our biotin preparation from liver.

Our results confirm the necessity of biotin, but differ sharply from those of Fraenkel and Blewett. This difference could arise from the different basic diets or from the different animal strains employed. The circumstance that our experiments and possibly those of the other authors were not conducted under aseptic conditions appears to us more important; thus, although no sign of infection was observed, living micro-organisms in the digestive tract could play an important part as producers of vitamins. One of us (H. R.) desires to acknowledge the assistance of the "Roche" Studien Stifting, which enabled him to take part in this work.

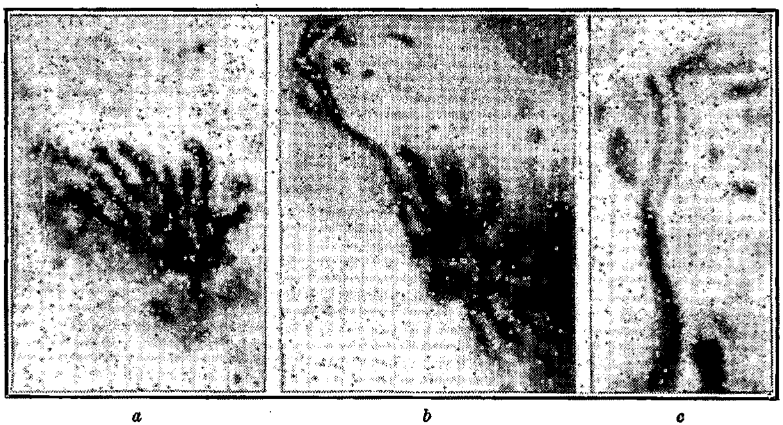
Demonstration of the Telophase Split in Todea

THE time of chromosome splitting in a normal cell division is, and has long been, one of the most hotly controversial topics in the whole of cytology. Two extreme views hold sway. According to one, a chromosome is single at all stages of mitosis except prophase and metaphase, the split itself occurring at the end of rest (cf. Darlington[1], White[2], and others). According to the other, a chromosome is at no time single, the prophase split being already formed at the preceding telophase or earlier; indeed in some plants with large chromosomes, notably Trillium and Tradescantia, both pro- and telophases have recently been described as visibly quadripartite (cf. Nebel[3] for the most recent available summary of this point of view).

Historically, both views go back to the last century, as may conveniently be seen by comparing early and late editions of a classic handbook such as that of Wilson on the cell[4]. Throughout this period the factual basis of both views has suffered repeated confusion and contradiction owing to uncertainties in other fields; ignorance of the facts of spiral structure and preliminary difficulties regarding the morphology of chromosome pairing being two of the



PHOTOMICROGRAPHS OF SISTER NUCLEI NEAR THE CLOSE OF A MITOSIS IN A YOUNG PROTHALLUS OF *Todea barbara*, FROM A LIQUID MOUNT IN ACETOCARMINE. *a* AND *b* × 2000; *c* × 4000.

most outstanding causes of conflict. The controversy is of importance because its solution is indispensable to a clear understanding of many larger problems involving a knowledge of chromosome structure. The literature is far too voluminous to be quoted in detail though a guide to it will be found in the works above cited; but the present position may perhaps be summarized by the statement that the older and simpler 'prophase split' view is the one more frequently expressed by modern British writers though, perhaps significantly, the most emphatic expositions of it are to be found in works with a strongly theoretical bias. On the other hand, the observations carried out in the last decade on spiral structure of chromosomes, especially in Japan and in America, has led an increasing number of observers in those countries to accept the theoretically more complex 'telophase split' view.

A problem such as this can scarcely be approached with profit except in relation to new and incontrovertible evidence. Some evidence of this kind is thought to be contained in the accompanying photographs.

The photographs are from a cell near the close of the third division in the germinating spore of the fern *Todea barbara*. The specimen had been treated for spiral structure, fixed in acetic alcohol overnight and then mounted and squashed out of its cell wall in a drop of warm acetocarmine by momentary pressure on the coverslip. It was observed and photographed in this reagent after ringing the preparation, but was afterwards successfully brought into Canada balsam and is still available for study.

In the accompanying illustration, *a* represents the upper of two sister plates of chromosomes at late anaphase or early telophase. Beyond traces of spiral structure which will be described elsewhere it shows nothing remarkable. *b* represents the corresponding, lower, plate of chromosomes. It lies at a deeper focal level and appears to have encountered some mechanical impediment in the act of squeezing out of the torn cell wall, for two chromosomes (now lying somewhat across each other in the top left-hand corner of the picture) have been violently distorted by stretching. In one of these (the apparently longer) not only has the spiral become almost effaced by this process but also, more important, for a considerable distance near its end, two distinct and separate threads have been forced widely asunder. The significant part of this chromosome is shown at a higher magnification in *c*.

While freely admitting that the ease of separation of the two threads in this chromosome is likely, in part, to be due to the treatment, I find it impossible to believe that the split itself is an artefact, it being remembered that until the pressure was applied to the coverslip the chromosome was in the form of a complex spiral. I am therefore of opinion that this one specimen is conclusive evidence that the telophase split is a reality for the plant under investigation.

Further discussion of this and other conclusions to which the specimen gives rise will be dealt with elsewhere.

A Water-soluble Carcinogen Derived from 3 : 4-Benzpyrene

IN a note entitled "Photo-oxides of Carcinogenic Hydrocarbons", an account has already been given of the labile water-soluble materials produced from 3 : 4-benzpyrene by irradiating it in solution in benzene, and of some biological effects produced by them[1]. Similar materials were shown by Schulman and Rideal to be adsorbed on protein monolayers[2], and by analogy with their work on œstrogenic and hæmolytic substances, it appeared possible that the existence of such water-soluble derivatives might throw light on the mechanism by which tumours are produced by the insoluble parent hydrocarbon. Further investigation of the optimum conditions for the irradiation, in collaboration with Dr. B. Szigeti, of the Research Department of Messrs. Adam Hilger Limited, has made it possible to prepare more concentrated extracts from irradiated benzpyrene than were used in the earlier experiments, and these have proved to be carcinogenic.

1·5 ml. of a 1 per cent solution of 3 : 4-benzpyrene in benzene was diluted to about 20 ml. with a mixture of benzene and cyclohexane containing upwards of 20 per cent of benzene. (In view of the restriction of supplies of the pure solvents, the exact proportions have had to be decided on the basis of the materials available. Optimum results are obtained with 20 per cent benzene.) This solution was irradiated for 30 minutes in an open dish 260 cm.^{2} in area placed immediately below a neon-sensitized mercury lamp which gives almost pure monochromatic ultra-violet light of wave-length 2537 A.[3]. The remaining solvent was evaporated quickly in a current of air, and the dry residue was extracted with about 4 ml. of *M*/100 sodium bicarbonate solution. The extract was filtered free from unchanged benzpyrene and from insoluble products of the irradiation.

0·15 ml. of the filtrate was brushed into an area 2 cm. in diameter on the backs of ten mice from a stock in which no spontaneous tumours have occurred over a period of several years. 260 paintings have been given in fifty-four weeks. Five mice have developed tumours on the painted site, and in four cases so far examined histologically, these consisted of multiple keratinizing squamous cell carcinomas with small papillomas.

In order to exclude the possibility that the effect might be caused by the passage of colloidal benzpyrene through the filter, ten control mice have been painted simultaneously with a solution prepared in the same way but without the irradiation. The control has also been weighted against the experiment by adding acetone to the solution to ensure its rapid penetration into the skin. Five of the control animals have been examined (up to fifty-four weeks of painting): none of them has shown any cancerous or precancerous condition. It may therefore be concluded that the aqueous extract from 3 : 4-benzpyrene contains a carcinogen which is not the hydrocarbon itself.

This conclusion is supported by evidence obtained in experiments in which mice previously sensitized by applying a solution of benzpyrene in benzene have been painted on the same site either with the aqueous extract or, for control, with bicarbonate solution. Twenty out of twenty-eight experimental mice have developed tumours in periods varying from thirty-eight to fifty-four weeks of painting as compared with four of the twenty-eight control animals.

It is impossible at present to identify the active compound. The aqueous extract contains two main substances characterized, at *p*H 8, by absorption bands at 3600 A. and 2760 A. respectively, but all attempts to isolate them have led to decomposition. Similar—possibly identical—substances have been detected in the products of irradiation, under the same conditions as were described in the earlier note[1], of cholanthrene, 1 : 2 : 5 : 6-dibenzanthracene, phenanthrene, anthracene and of naphthaene. The absorption spectra exclude the possibility that they are either photo-oxides[4], mono- or dihydroxy derivatives[5], or of the stilbene type[6].

This work has been maintained by grants from he Medical Research Council, to which I express my indebtedness. I also thank Dr. H. B. Fell and Prof. E. K. Rideal for their continual advice and interest, nd Dr. A. Glucksmann for undertaking the histoogical examination of all the material.

Lichenin

THE introduction of cross-linkages into soluble synthetic linear high polymers is followed by a decrease in solubility. In Nature, an interesting parallel appears to be afforded on one hand by the water-soluble polysaccharide lichenin, which consists of an unbranched β-glucopyranose chain $(C_6H_{10}O_5)_n$ where $n = 80–160$ [1, 2] and by cellulose on the other, if for the latter the structure of β-glucopyranose chains (or multi-membered loops) linked at intervals by cross-linkages[3] be accepted. This communication contributes to the question of the structural difference between lichenin and cellulose.

It has been shown previously[4] that treatment of potassium hydroxide-cellobiose with dry methyl sulphate followed by hydrolysis yields 2-methyl- and 2 : 6-dimethyl glucose whereas potassium hydroxide-cellulose when treated in this way yields 2-methyl glucose, but no 6-methyl or 2 : 6-dimethyl glucose[5]. This seems to indicate that in cellulose the primary alcohol residues are not vulnerable to attack under these mild conditions, and is evidence that the primary alcohol residues are the most likely to be involved in some form of cross-linking between the chains.

We have now shown that lichenin can combine with one molecular proportion of potassium hydroxide for each anhydroglucose unit to form an unstable addition compound, but that both 2- and 6-methyl glucose are present in the products of hydrolysis after methylation under anhydrous conditions. This result may be interpreted as showing that the primary alcohol groups in lichenin are not shielded as in cellulose and is in harmony with the results of Carter and Record[1] who, by their osmometric measurements on acetylated and methylated lichenins, show that the 'physical' molecular weight is of the same order as that found by end-group assay; that is, there is no aggregation of primary chains by cross-linkages, and thus agrees with the suggestion of W. N. Haworth[3].

Artificially Induced Loss of Theta-Toxin Production by *Clostridium welchii* Types *A* and *C*

Macfarlane and Knight[1] having shown fairly conclusively that the alpha toxin of *Cl. welchii* Type *A* is a lecithinase, we considered it possible that repeated passage through media containing lecithin might enhance the capacity to produce alpha toxin. However, we found that after a dozen rapid passages through Hall's cooked-brain medium, strains showed no loss of capacity to produce alpha toxin when grown in 'test medium' (V.F. broth plus 0·25 per cent glucose), as compared with the same strains after similar passaging through test medium, but that they unexpectedly lost the capacity to produce theta toxin. It would thus appear possible to produce large quantities of *Cl. welchii* toxins free from theta toxin, much more simply than by the procedures described by van Heyningen[2]. Strains of *Cl. welchii* Type *C*, which normally produce considerable amounts of theta toxin (up to 1,000 H.U. per ml.), behaved in the same way.

It is of some interest to note that this procedure did not at all affect the capacity of Types *A* and *C* to produce proteinase. This suggests that theta toxin is not identical with the gelatinolytic proteinase, which, like it, is activated by cysteine.

The E. M. F. of Thermal Fluctuations in Resistances

THE formula giving the mean-square E.M.F. of thermal fluctuations per cycle, in a resistance R at temperature T, namely:

$$\overline{e_\nu^2} = 4 . R . k . T, \qquad (1)$$

was first derived by Nyquist[1] by thermodynamical reasoning.

J. Bernamont[2] has derived formula 1 from the corpuscular point of view, using the Lorentz theory of electrons. The mechanism of the conductivity by free electrons was considered, both with the classical statistics of Boltzmann and the quantum statistics of Fermi-Dirac.

C. J. Bakker and G. Heller[3] have shown that to specify Boltzmann or Fermi-Dirac statistics is unnecessary and that equation 1 can be obtained by application of the most general statistical consideration. The following derivation of (1), using macroscopical considerations for conductors satisfying Ohm's law, is based on the equipartition of energy.

Consider a conductor, the total charge of which is zero, with no applied external electric field. Though on the average the total charge is zero, the density of charge at any point in the conductor may fluctuate; an excess of negative charge at one point is counterbalanced by an excess of positive charge at some other point or points of the conductor. The 'equation of continuity', using the rationalized system of units, is:

$$\nabla . \vec{J} + \frac{\partial \rho}{\partial t} = 0, \qquad (2)$$

where $\vec{J}$ is the current density and ρ is the density of charge. For conductors satisfying Ohm's law, we have:

$$\vec{J} = \sigma . \vec{E}, \qquad (3)$$

where σ is the conductivity and $\vec{E}$ is the intensity of the electric field. Equation 2 becomes:

$$\nabla . \sigma \vec{E} + \frac{\partial \rho}{\partial t} = 0. \qquad (2a)$$

If the conductor is homogeneous and isotropic, then:

$$\nabla . \vec{E} = \frac{1}{\varepsilon} \rho, \qquad (4)$$

where

$$\varepsilon = \varepsilon_0 K_0 \qquad (5)$$

is the specific inductive capacity of the medium, ε_0 is relative to free space, and K_0 is the dielectric constant. Combining equations 2*a* and 4, we have:

$$\nabla \left(\frac{\partial \vec{E}}{\partial t} + \frac{\sigma}{\varepsilon} \vec{E} \right) = 0. \qquad (6)$$

We are interested only in the time dependence of $\vec{E}$, and as the conductor is homogeneous and isotropic, we take as solution of equation 6:

$$\frac{\partial \vec{E}}{\partial t} + \frac{\sigma}{\varepsilon} \vec{E} = 0, \qquad (7)$$

the integration constant being zero, since the applied external field is zero. (The final results are valid for a constant external field.)

Equation 7 is interpreted as follows: owing to the fluctuations of the density of charge, there results a fluctuating electric field. If at any instant the field is E_0, it will decay according to equation 7 with a time constant $\tau = \varepsilon/\sigma$, which is exceedingly small, namely, 2×10^{-10} sec. for sea water and 2×10^{-17} sec. for copper.

Using equation 7 to form the 'correlation function' $\overline{EE_t}$, one has[2] for $t > 0$:

$$\overline{EE_t} = \overline{E^2} . \exp\left(- \frac{\sigma}{\varepsilon} . t \right). \qquad (8)$$

The 'spectral component of intensity' for 'infinitely brief' correlations, that is, for frequencies $\nu << \frac{1}{2\pi\tau}$, we have

$$\overline{E_\nu^2} = 4\overline{E^2} \int_0^\infty \exp\left(- \frac{\sigma}{\varepsilon} . t \right) . dt = 4 . \frac{1}{\sigma} . \varepsilon \overline{E^2}. \qquad (9)$$

Assuming the conductor is cylindrical, of section s and length l, then

$$\overline{E_\nu^2} = \frac{4}{\sigma . s . l} . \varepsilon \overline{E^2} . s . l. \qquad (10)$$

$\varepsilon . \overline{E^2} . s . l$, in the system of units used, is the total mean energy of the electromagnetic field. Allowing $\frac{1}{2}kT$ per degree of freedom (the electric and the resulting magnetic fields) then:

$$\overline{E_\nu^2} = \frac{4}{\sigma . s . l} . kT. \qquad (11)$$

Finally, the mean-square E.M.F. of fluctuations per cycle, across the ends of the cylindrical conductor, is

$$\overline{e_\nu^2} = \overline{E_\nu^2} . l^2 = \frac{4l}{\sigma . s} . kT = 4R . k . T, \qquad (12)$$

where $R = \frac{l}{\sigma . s}$ is the resistance of the conductor

Energy-Level Treatment of Reaction Data

IN a recent paper[1] it was shown that satisfactory explanations of certain aromatic side-chain reaction data are provided by correlation of the alterations in electron density which arise from the various electron displacements (inductive, inductomeric, mesomeric and electromeric) of the substituents with the energy-levels in the initial, transition and final states of the reaction. Such changes, relative to the energy-levels in the unsubstituted parent molecule as a reference standard, were represented by assigning arbitrary numerical values to each polar effect and thus obtaining a quasi-quantitative expression of their resultant effects on the activation energy of the reaction.

In the absence of data regarding the absolute magnitudes of the various polar effects such numerical values were, of necessity, somewhat arbitrary and in unknown units, although both in their signs and *relative* magnitudes, they satisfied the known order of electron release or attraction by the various mechanisms.

A recent paper by Audsley and Goss[2] has now provided reliable values for the primary (μ_P), induced (μ_I) and mesomeric (μ_M) dipole moments of the four monohalogenobenzenes. This data should provide at least approximately *quantitative* values for the corresponding electron displacements in the reaction previously used as an illustration[1], namely, the Menschutkin reaction

$$p-X.C_6H_4.CH_2.Br+C_5H_5N \rightarrow X.C_6H_4.CH_2.\overset{+}{N}C_5H_5\}\overset{-}{Br}.$$

The only magnitudes which must still remain hypothetical are those (*a*) of the electromeric (+ *E*) effect and (*b*) of the reduction in the inductive (− *I*) effect, of the halogen substituent in the transition state. Changes in energy-levels due to permanent polarization effects will be proportional to some (unknown) constant multiplied by μ. Using the same values for the two unknowns as those previously employed, but substituting the values of $10^2 \mu$ (which give whole numbers of convenient magnitudes) for the various permanent polarizations, the following results are obtained:

RELATIVE ENERGY-LEVELS IN THE REACTION

$$p-X.C_6H_4.CH_2.Br+C_5H_5N \rightarrow X.C_6H_4.CH_2.\overset{+}{N}C_5H_5\}\overset{-}{Br}$$

	Reduction in energy-levels in the ground state				Reduction in energy-levels in the transition-state					$E_g - E_a$
X	μ_P	μ_I	μ_M	Total (Eg.)	μ_P	μ_I	μ_M	E	Total (Eg)	
H	—	—	—	—	—	—	—	—	—	Reference standard
Cl	−184	−75	+95	−164	−184	−74	+95	+2	−161	−3
Br	−172	−70	+74	−168	−172	−69	+74	+4	−163	−5
F	−176	−72	+104	−144	−176	−65	+104	~0	−137	−7
I	−156	−64	+51	−169	−156	−63	+51	+7	−161	−8

It will be seen that the new values predict exactly he same order for the velocities of the various -halogenobenzyl bromides as that previously indiated, namely, activation energies decreasing in the order H > Cl > Br > F ≈ I, in agreement with the xperimental velocity sequence I ≈ F > Br > Cl > H. This agreement, using magnitudes which have a definite physical basis, strongly supports the essential correctness of the whole method of energy level treatment of reaction data and also suggests that the numerical values assigned to the electromeric effects probably give an approximate estimate of the *relative* magnitudes of these effects for the halogen group of substituents.

Agricultural Research Institutes and the Future

DR. B. A. KEEN's article in NATURE of September 5, p. 282, does well to invite the attention of research workers to the possible future developments in agricultural education and research in Great Britain. It may be regretted that Dr. Keen sought to restrict his remarks to arable agriculture. I venture to hope, with Sir George Stapledon, that our future agriculture will be ley farming, and that most of our farmland will cease to be classifiable into the rigid categories of 'grass' and 'arable'. This, however, is a minor point.

Dr. Keen's suggestion for co-ordinated field experimentation may be warmly welcomed, and I would stress the importance of ensuring that research localities be carefully chosen to cover the principal classes of soil. Too often in the past, expensive and well-planned field experiments have been laid down without reference to soil type. Unfortunately, the national soil survey has not been in progress long enough for even a preliminary soil map to be made; but a considerable amount of information is available, and it would not be difficult to examine the suitability of proposed experimental areas in order to avoid the selection of non-typical sites.

Finally, although co-ordination of post-war agricultural research is inevitable, it may be hoped that the organization will not be too rigid. If a compromise is necessary between a system of complete freedom for the individual investigator and a totalitarian research system, let us err on the side of freedom even at the risk of a certain amount of overlapping.

RESEARCH ITEMS

Insect Fauna of Lower California

THE peninsula of Lower California has an interesting insect fauna that has been long neglected by students. The terrain is possibly largely accountable, owing to the difficulties of collecting in such a desert region with its barely passable roads. It is consequently understandable that most insect collecting has been made in the Cape Region, which can be easily reached by boat. The California Academy of Sciences has been the leader in the biological exploration of Lower California but unfortunately its collections, made between 1888 and 1894, were largely destroyed in the great San Francisco earthquake and fire. Realizing the need for further collecting, Messrs. A. E. Michelbacher and E. S. Ross spent two months on the Peninsula in 1938 and the collections obtained seemed sufficiently large to make desirable the publication of a series of entomological reports in the *Proceedings of the California Academy of Sciences*. Of these reports six have already been published during 1942 up to June 20 and deal with an introductory account, the Cerambycidæ, Buprestidæ, Myrmelionidæ, Symphyla and Culicidæ. The authors are (respectively) A. E. Michelbacher and E. S. Ross, E. Gordon Linsley, E. C. Van Dyke, A. E. Michelbacher and T. H. G. Aitken. Several new species have been brought to light, particularly among the Cerambycidæ where they number 22 species out of a total of 116 species collected. From among the 58 species of Buprestidæ recorded eight are new and a similar number of new Myrmelionidæ are recorded.

Parasites of Shisham Defoliators in the Punjab

Indian Forest Records (N.S. Entomology, 7; 1942) contains a contribution entitled "On the Biology of the Parasites of the Shisham Defoliators in the Punjab Plantations" by R. N. Mathur with a note by C. F. C. Beeson. It appears that the defoliation of the shisham trees (*Dalbergia sissoo*) in the irrigated plantations presents several features of unusual ecological interest. The principal defoliators are caterpillars of the Noctuid moth, *Plecoptera reflexa* Guen., which, in turn, are attacked by 18 species of primary parasites. Defoliation by this insect, and certain other species, is epidemic annually because stands of poor-quality shisham on unsuitable sites form permanent foci of infection. Furthermore, stands of shisham that have not tapped the moisture-level in the deep subsoil come into leaf late. Also, shallow, frequent irrigation causes the defoliated trees to produce new foliage at a periodicity that conforms to the sequence of generations of *Plecoptera reflexa*. Defoliation can be controlled by restricting shisham to areas suitable for it and stocking unsuitable sites with other species. It is important to ensure that the taproots of shisham cuttings reach the subsoil moisture level in one or two seasons by means of deep controlled irrigation. Control of natural enemies follows automatically when stands are established under the foregoing principles. It is clear that the parasite population-density will be maintained at a higher level under improved conditions of shisham cultivation. Until such an improved environment is attained it is of little use attempting to introduce non-indigenous parasites as aids in the control of defoliators.

Mouth-parts of a Weevil (*Calandra granaria*)

DR. R. DENNELL has given an account of the above subject together with the rostrum and fore-intestine (*Phil. Trans. Roy. Soc.*, **231**, 247; 1942). It is probable that many of his deductions will apply to numerous other weevils of similar behaviour. It appears that the mandibles are asymmetrical and possess a markedly oblique axis of rotation and by this means the action of the teeth becomes determined. The so-called pharyngeal bracons reach their highest degree of development in Calandra and its allies, where they form long slender rods that extend freely almost the whole length of the pharynx. They are attached to the mandible of their side and are wrapped around the tendon of the adductor muscle. The working of the molar teeth of the mandibles in an antero-posterior direction causes the pharyngeal bracons, that are attached closely behind them, to move to and fro in the pharynx. It is by the frequent repetition of these movements that the bracons are responsible for the progressive transport of the food along the pharynx. A median tract of spines in the pharyngeal roof, it may be added, co-operates in the backward passage of the food. The paper is fully illustrated and provides the first connected account of the functions of the bracons just alluded to.

Histology of Mammalian Hair

THE importance of fibre histology in forensic science was pointed out, and processes involved in the identification of animal hair outlined by J. L. Stoves in a paper read to the Society of Public Analysts and other Analytical Chemists on October 7. Photomicrographs were shown to be of value for reference purposes and also as a means of presenting evidence in court. A description was given of new methods employed for the preparation of photomicrographs of (*a*) transverse sections, (*b*) longitudinal sections, (*c*) cuticular scale impressions. New features of apparatus were illustrated, and a number of photomicrographs shown demonstrating the histological features of various mammalian fibres.

Biochemistry and Genetics

E. L. Tatum and G. W. Beadle (*Proc. Nat. Acad. Sci.*, **28**, 235; 1942) have utilized their X-ray mutant of *Neurospora crassa* to study the synthesis of *p*-amino-benzoic acid. The mutant strain is unable to synthesize the vitamin. When supplied with this vitamin the mutant strain grows at the same rate as normal and reacts like the normal strain when sulphanilamide is given to the medium. The mutant differs from the normal strain by a single gene unlinked with sex and situated far from the centromere. The gene is concerned with the synthesis of *p*-amino-benzoic acid and presumably influences a single synthetic process. It is concluded from tests with related substances that the bio-synthesis does not involve the introduction of an amino group into a preformed benzene ring.

Genetics and Eye-movement

THE act of reading involves ocular shifts and pause at each line of print. These can be recorded by instruments, and it is found that the pattern of the eye movement is remarkably individualistic. By studying the eye-movement of twins H. E. Jones and D. H. Morgan (*J. Hered.*, **33**, 167–72; 1942) show that in addition to the habit differences in reading induced by training there are inherited differences. Identical twins often show as close a similarity in eye-movement pattern as between two records of one individual, whereas classroom mates who have been trained alike and who are similar in reading ability show marked differences in specific aspects of eye-movement.

Salivary Gland Chromosomes in Mosquitoes

EILEEN SUTTON (*Proc. Nat. Acad. Sci.*, 28, 268; 1942) shows that salivary gland type chromosomes may be found in the Malphigian tubes of *Culex pipiens* and *Ædes ægypti*. There do not appear to be heterochromatic regions as in Drosophila but the banded regions could be mapped quite well. There is a well-marked nucleolus in *C. pipiens* but in *Ædes ægypti* it is only observed in early stages. The banding of the chromosomes is not present in the earlier stages, but the nucleic acid is accumulated in globules, after which the nucleic acid would appear to be redistributed to form the banded structure. It will be remembered that drastic treatment with Kodani's process gives the reverse effect—concentration of the nucleic acid from the banded parts into globules.

Synthesis of Vitamins by Intestinal Bacteria

P. R. Burkholder and I. McVeigh (*Proc. Nat. Acad. Sci.*, 28, 285; 1942) demonstrate that several bacteria normally living in the intestines of higher animals synthesize biotin, riboflavin, thiamin, and nicotinic acid when grown in media free from these vitamins. The bacteria studied were *Eschericia coli, Proteus vulgaris, Bacterium aerogenes, Alkaligenes fecatis, Bacillus mesentericus* and *B. vulgaris*. *P. vulgaris* appeared unable to synthesize nicotinic acid and *B. mesentericus* is deficient in biotin. The amount of vitamin produced at 36° C. was greater than required by the bacteria; it was found that 1–15 per cent of the biotin and nicotinic acid present in forty-eight hour cultures may occur outside the bacteria. The greatest synthesis of vitamins would appear to occur during the first fourteen hours of growth.

Micro-determination of Calcium in Serum

THE procedure of Clark and Collip, which is widely used in clinical laboratories for the micro-determinaion of calcium in serum, is admittedly subject to a number of errors but was so designed that they should ancel one another. P. F. Holt and H. J. Callow, in paper read to the Society of Public Analysts and ther Analytical Chemists on October 7, find that such cancellation of errors does in fact occur provided the Clark-Collip procedure is strictly adhered to and the calcium content of the serum is normal. They describe a micro-procedure in which the errors are eliminated and which has the advantages of ease of manipulation, reduction in time of operation and applicability to smaller volumes of serum.

Preparation and Analysis for Iron of Hæmin and Hæmoglobin

AFTER a short reference to the problem of standardizing estimations of hæmoglobin in blood, G. E. Delory, in a paper read to the Society of Public Analysts and other Analytical Chemists on October 7, described procedures for the preparation of, and estimation of iron in, hæmoglobin and hæmin. Two analytical methods were described. In one the sample is incinerated after being moistened with nitric acid, the ash is dissolved in hydrochloric acid and the iron titrated with titanous chloride solution. The other, based on the colorimetric method of R. W. Thorp, depends on measurement of the colour produced by the reduced iron with $\alpha\alpha'$-dipyridyl. A photo-electric colorimeter particularly suitable for the method was exhibited by Dr. E. J. King.

Synthesis of Cellobiose

ALTHOUGH a synthesis of cellobiose was achieved by Freudenberg and Nagai in 1933 the yield was poor and there still remained the problem of obtaining a structurally definitive synthesis of the disaccharide. W. T. Haskins, R. M. Hann and C. S. Hudson (*J. Amer. Chem. Soc.*, 64, 1289; 1942) have now prepared synthetic epi-cellobiose octa-acetate from products derived from D-mannose and D-glucose (both synthesized by Emil Fischer), and converted it into cellobial hexa-acetate, which on oxidation with perbenzoic acid gave chiefly cellobiose hexa-acetate; this product on acetylation gave a 63 per cent yield of a crystalline mixture of α- and β-cellobiose octa-acetates, from which crystalline cellobiose was obtained in quantitative yield by deacetylation. The overall yield was 35 per cent.

'Heavy' Adrenaline

DEUTERIUM (heavy hydrogen) has been used as an indicator in biological experiments with the assumption that the substitution for protium (light hydrogen) causes no change in physiological action, and this is probably correct, although Erlenmeyr and Lobeck in 1937 reported that acetylcholine bromide in which the acetyl hydrogens were replaced by deuterium became slightly less active. G. R. Clemo and G. A. Swan (*J. Chem. Soc.*, 395; 1942) have prepared 'heavy' *dl*-adrenaline from 'heavy' catechol of approximate formula $C_6HD_5O_2$ and chlorodideuteroacetic deuteracid, forming 'heavy' chloroacetocatechol, which with a solution of trideuteromethyldideuteramine in deuterium oxide gave 'heavy' *dl*-adrenaline containing 90 atoms per cent of D. Physiological tests showed an elevation of blood pressure almost indistinguishable from that produced by a similar amount of 'light' *dl*-adrenaline, the replacement of protium by deuterium in this case producing little (if any) change in the physiological action.

Long-chain Acids containing a Quaternary Carbon Atom

BRANCHED-CHAIN fatty acids are scarce in natural products and those known are mostly related to terpenes. Oils of Hydnocarpus and related species, naphthenic acids from petroleum and fatty acids isolated from *Mycobacterium Lepræ* and *M. tuberculosis* (formerly regarded as toxins) are examples. A. J. Birch and Sir R. Robinson (*J. Chem. Soc.*, 488; 1942), who review previous work in the field, now describe the preparation of several acids containing a quaternary carbon atom, namely, trisubstituted acetic and propionic acids. The surface film behaviour of the substances and biological tests are only briefly reported. The synthetic methods, however, are fully described. Special attention was paid to the use of $\alpha\alpha$-dialkylsuccinic and $\beta\beta$-dialkylglutaric acids as intermediates, and also to the application of the Michael reaction to appropriate $\alpha\beta$-unsaturated ketones. Some acids prepared were 2 : 2-dimethyl-lauric acid, 2 : 2-dimethylstearic acid, 1-methyl-1-*n*-octyldecoic acid, 3 : 3-dimethyl-tetradecoic acid, 5-keto-3 : 3-dimethyl-lauric acid and 2-phenacyl-2-methyl-lauric acid.

EARTHQUAKES IN NEW ZEALAND

A VERY important review of New Zealand earthquakes by Dr. J. Henderson, director of the Geological Survey of New Zealand, and Mr. R. C. Hayes, acting-director of the Dominion Observatory, Wellington, New Zealand, has been issued*. Compared with other countries in which earthquakes are common, the frequency of earthquakes in New Zealand is relatively high. This is due to the occurrence of a large number of semi-destructive earthquakes and comparatively few major destructive earthquakes. During the years 1835–1934, there were 69 New Zealand earthquakes, of which 6 reached intensity 10 on the Rossi-Forel scale, 14 attained intensity 9 on the same scale, and the remainder were of smaller intensity. During the twenty years from 1921 until 1940 inclusive there has been an average of approximately 260 earthquakes felt in the islands each year, the average maximum intensity of the greatest shocks being rather more than 8 (semi-destructive) on the Rossi-Forel scale. During the year 1922 there were 1,187 earthquakes felt, but this abnormally large number was due to the Taupo earthquake swarm. The aftershocks of the Buller earthquake of June 17, 1929, also caused the total numbers in 1929 and 1930 to be greater than normal.

New Zealand may be divided roughly into four seismic regions:

(1) All areas of the North Island east and south of an approximate line from the vicinity of Whakatane in the Bay of Plenty to the vicinity of Hawera in South Taranaki, and all areas of the South Island north of an approximate line from the vicinity of Hokitika on the west coast, through the region of Lake Coleridge, to Banks Peninsula. During the years 1921–40 this region had an average of 97·8 earthquakes per year, 4·1 per decade of which were semi-destructive, and 1·7 per decade destructive (R.F. 9–10).

(2) South Auckland, western Bay of Plenty, Waikato, and Taranaki (except the southern portion). During the years 1921–40 there was an average of 23 earthquakes per year, of which 1·1 per decade were of intensity R.F. 8 (minor destructive) and there was none of greater intensity. The activity in this region tends to increase gradually towards the east and south, where it merges into region 1.

(3) Areas of the South Island, south of the boundary of region 1. In this region between 1921 and 1940 there were 12·1 earthquakes per year, of which 0·1 per decade were semi-destructive (R.F. 8), and none of greater intensity. Only one semi-destructive shock has been definitely recorded in this region (near Mount Cook), though early history suggests that heavy shocks occurred in the West Coast Sounds region in the years 1792, 1810, 1826–27. The eastern side is definitely less seismic than the western.

(4) Areas north of Auckland. In this region during the years 1921–1940 there was an average of 1·1 earthquakes per year, of which none reached intensity 8 on the Rossi-Forel scale. No destructive shocks have been known to occur in this region.

It is emphasized that these regions are approximate and that one region merges into its neighbours. Taken in conjunction with the geology of New Zealand, the above facts are most instructive, and apart from the geology they can scarcely be comprehended. Earthquake and volcanic activity are manifestations of the adjustments constantly occurring in the earth's crust. Around the great sunken area of the Pacific there is a more or less continuous belt of geologically recent mountains, and this belt as a whole is subject to "chronic and acute seismicity". Earthquakes sometimes happen within the belt itself, though a large proportion have their epicentral areas on its submerged frontal slope. Dr. Henderson states that the South Island of New Zealand and the eastern part of the North Island are on the crest of the great mountain ridge or crustal fold which forms a portion of the real border of the Pacific. This ridge maintains a relatively straight course north-north-east for 1,600 miles across the floor of the Pacific, nearly to Samoa. The Auckland Peninsula, part of a decidedly weaker fold, meets the main fold nearly at right angles in the Rotorua-Taupo volcanic region. The earthquakes of this seismically sensitive district, though they may be locally severe, are not usually felt far from their points of origin. On the other hand, the tectonic earthquakes that occur along the main earth-fold shake large areas, some of them being recorded on instruments throughout the world. These are caused by slipping of earth-blocks against their neighbours along fractures.

Many great fault-zones have been traced for long distances, but a few only have been active since European occupation. The Hawke's Bay earthquake of 1931 raised an area 60 miles long and in parts 10 miles wide in a north-east direction. The uplift was greatest along the south-east edge of the area, for miles amounting to 6 ft. or more. Numerous levels on the Heretaunga Plain and along the railway north of Napier showed that the uplift decreased north-westward, so that the area was slightly tilted in that direction. The ground east of the uplifted area sank, and parts of the Napier and Wairoa flats are more than a foot lower than before the earthquake.

In 1929, movement along a north-trending fault seven miles west of Murchison raised the ground east of the fault by about 15 ft., and caused it to shift north-west by about 9 ft. The uplift gradually decreased eastward and died out sixteen miles from the fault, facts indicating a slight tilt of the earth-block towards the east. Subsequent levellings showed that the block was sinking somewhat irregularly, a movement, no doubt, which caused some of the innumerable local after-shocks felt in the area over many months after the main shock.

Other sensible earth-movements occurred in connexion with the Taupo earthquake series of 1922 the Amuri earthquake of 1888, the Wellington earthquake of 1855, and probably the Awatere earthquake of 1848. There is also definite evidence of geologically recent differential movement of earth-blocks at several widely separated points in both Islands. Seismographs situated at Wellington, Auckland, Christchurch, Arapuni and New Plymouth registered four strong distant earthquakes during July 1942 (Provisional Bulletin, No. P 125). These were on July 7 8, 25 and 29. Additionally there were nineteen sensible shocks in the islands, none being greate than intensity 4 on the Rossi-Forel scale. Th greatest of these was on July 26 and was felt with intensity 4 (R.F.) in the western areas of North Island and the northern parts of the South Island.

SOCIAL BIOLOGY IN EDUCATION

A CONFERENCE on the place of social biology in education was held by the British Social Hygiene Council at Tavistock House, London, W.C.1, on October 24.

Sir Cyril Norwood, giving the presidential address, made no claim to be a biologist, but stated that during his forty years of educational work he had been increasingly impressed by the importance of biology in education. One of the implications of social biology is that sex education should be regarded as a normal part of the school curriculum. Sir Cyril made some chastening remarks about those who see the solution in the making of biology a compulsory subject in the School Certificate, remarking that he has a list of at least fourteen subjects which could make a similar claim. Further, deploring the fact of the ridiculously high standards of the university scholarships examinations and referring to the method of selection of sixth-form biologists, he emphasized that primary school pupils, being by far the most numerous, constitute the most important aspect of the problem. New advance after the War will inevitably be a matter of decades, particularly in view of the fact that a hundred thousand extra teachers will have to be found and trained. In this connexion the universities will have to face up to their responsibility in the training of teachers, especially by the provision of general honours courses, including biology and social science with a biological basis.

Later in the morning Mr. W. L. Sumner spoke on "Social Biology Now and in the Future". Referring to the annual decline taking place in the mean national intelligence quotient, he mentioned the need for considering eugenic measures. He pointed out that biologists to-day have sufficient knowledge to enable them to produce a biscuit containing adequate vitamins and minerals to satisfy daily needs, but in this as in other respects it is the economic application of biological knowledge that is faulty. In subsequent discussion Mr. David Jordan pointed out the need for democracy in the functioning of the school. Miss Taylor emphasized the importance of habit formation n the primary school, followed by a well-integrated general science course in post-primary schools. Other speakers referred to the results of the application of biological knowledge in the U.S.S.R. and the need for providing the people of Great Britain with an deal for which they will feel enthusiasm.

The afternoon session was opened by an address by Sir John Graham-Kerr. He gave an account of he life among the South American Indians of the Gran Chaco. He sketched their system of education, including education through the years of adolescence in preparation for adult life. The alertness which is he constant condition of primitive man contrasts very markedly with the unthinking automatism of he product of modern education. He pointed out hat the mere indiscriminate collection of facts is no more science than the heaping up of bricks is architecture, and stressed the importance of intermingling poetry and imagination with the accurate establishment of fact. The muscular performance of a skilled craftsman is just as much a manifestation of 'brain power' as is the production of the most erudite thesis. He deprecated the common tendency to regard manual work as in some way inferior to mental.

Mrs. E. J. Hatfield opened a discussion on "Social Biology for Teachers in Training", by stating that German university students in Munich and Nuremberg before the War of 1914–18 had no critical faculty whatsoever, and that she does not know of any educational system better than the English. In making plans for post-war training of teachers much thought must be given to the majority of the profession, namely, those who were trained many years ago. This would involve refresher courses lasting for at least a term, with full salary during attendance, in addition to the shorter refresher courses at frequent intervals. It has been her impression while lecturing that a training college student has, in general, a far greater social sense than the academic graduate teacher in the secondary school. The subject of hygiene in the training college, which is compulsory for all students, should include the fundamentals of biology together with its social implications, and in the universities there should be a social biology course for all graduates who intend to take up teaching.

In the discussion which followed, Miss Warden confessed an inability to understand exactly what is meant by the phrase 'social biology', but made a plea for greater co-operation between the medical and teaching professions, particularly in the provision of specialist knowledge on medicine to teachers and on education to medical people. Later in the afternoon Mr. C. Bibby mentioned that in January the Central Council for Health Education would be publishing the first number of a quarterly journal, *Health Education*, to meet precisely this need.

The evening session on "Our Responsibility for Human Quality in the Colonial Empire" was opened by Sir Francis Fremantle, giving population statistics from various countries. He quoted various conditional forecasts of population trends and mentioned that the real cause of the decline in the birth-rate is the decay of moral authority of parents, teachers and religion together with the fundamental economic conditions of acquisitive society. The Maoris were given as an example of recovery after apparently inevitable extinction, and the depopulation of Melanesia as a warning of what can happen when white men interfere with native methods of life.

PLANKTON OF THE NORTH SEA*

PHYTOPLANKTON of the North Sea is being investigated very thoroughly by examination of the continuous plankton records collected by the Oceanographical Department in the University of Hull. Earlier results were published in the Department's *Bulletin* in 1940 (for the years 1932–37), and the Diatoms for 1938–39, corresponding to the present part, in 1941. The distribution of the Dinoflagellates and Phæocystis in general provides further evidence of the points made in the preceding diatom paper. A picture has gradually been growing of the distribution of the phytoplankton in the area investigated, at first only in the north, later in the central and southern North Sea. Six extra steamship lines were run monthly: from Hull to Oslo, from Leith to Hamburg, Copenhagen and Lerwick, and from Pentland Firth to Hamburg and Bergen. In addition, records were obtained from the Faeroe Shetland Channel in 1939, the route crossing the southern entrance to the Faeroe–Shetland Channel and stopping some hundred miles past the Faeroe Bank. It is most unfortunate that all these valuable activities have necessarily been stopped by the War.

---

* Phytoplankton of the North Sea, 1938–39. Part II—Dinoflagellates, Phæocystis, etc., by C. E. Lucas. The Faeroe-Shetland Channel, 1939, by C. E. Lucas, N. B. Marshall and C. B. Rees. *Hull Bulletins of Marine Ecology*, edited by A. C. Hardy and C. E. Lucas, Nos. 9 and 10, 2, pp. 47–94. Plates XXXIX–LXII. April, 1942. 8s.

This later dinoflagellate work differs from the previous reports in dealing to a certain extent with the separate species of Ceratium. *Ceratium fusus* is the most important of these, is usually much the most numerous and tends to determine the apparent distribution of the genus. At times it forms almost 'pure' communities. Increase in Dinoflagellates always follows that of the Diatoms. Phæocystis is usually abundant when there are fewer Diatoms and Dinoflagellates. The importance of 'patchiness' in all three groups is emphasized and also the rapid numerical change in relatively short time and space intervals. In the southern area between 1932–37 and 1938–39 it is found that after increasing until 1937 or 1938, the Diatoms and Dinoflagellates were much scarcer in 1938 and/or 1939, but Phæocystis was scarcer from 1934 until 1937 and increased again during 1938–39. On the whole, the flagellate data provide confirmatory evidence for the cycle of changes since 1932 which were first deduced from the diatom record up to 1937 and 1939, and have already received some confirmation from the zooplankton for the earlier period.

The persistence of the two large areas of dinoflagellate production in the north-west and south-east provides even better evidence than in the Diatoms of the general agreement between the adjacent and intersecting recorder lines.

It is very interesting that there are signs of relationship between the distribution of some of the Dinoflagellates in the north-western area and that of *Sagitta elegans elegans*, and this seems to point to a possible association between the organisms found in this area and the Atlantic influence that may be extended there. The north-western area corresponds broadly with Russell's (1939) area of "*elegans* water" and the south-eastern to his area of "coastal water". The distribution shown of the Ceratium species together with the Diatoms may possibly be associated with signs of an increased flow of (possibly phosphate scarce) water into the area from the English Channel after the early months of 1938. More evidence is provided suggesting that the phytoplankton-productive water of the preceding years may have moved out of the area in a northerly or north-easterly direction.

The results of the Faeroe-Shetland Channel line are very suggestive but much more data are required to bring the work into line with the rest. They do, however, provide for the first time a series of continuous records at fairly short intervals from spring to midsummer, and form a basis for future work.

FORTHCOMING EVENTS

(Meeting marked with an asterisk is open to the public)

Saturday, November 7

BIOCHEMICAL SOCIETY (in the Department of Organic Chemistry, Imperial College of Science and Technology, South Kensington, London, S.W.7), at 11 a.m.: Discussion on "The Theory and Application of Chromatographic Methods to Biological Problems".

Saturday–Sunday, November 7–8

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX (at the Royal Society, Burlington House, Piccadilly, London, W.1).

Saturday

At 11 a.m.: Annual General Meeting. At 12 noon: Sir Richard Gregory, Bart, F.R.S.: "International Systems and Standards".

Sunday

At 10.30 a.m.: Symposium on Microfilm.

Monday, November 9

FARMERS' CLUB (at the Royal Empire Society, Craven Street, London, W.C.2), at 2.30 p.m.—Dr. H. I. Moore: "The Cropping Problem of To-day".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Capt. R. C. Farrow: "Forecasting Run-off from Snow Surfaces".

Tuesday, November 10

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 3 p.m.—Sir James Jeans, O.M., F.R.S.: "Evolution in Astronomy", 2.*

ASSOCIATION OF SCIENTIFIC WORKERS (at the Royal Photographic Society, 16 Princes Gate, South Kensington, London, S.W.7), at 6.30 p.m.—Projection of the Cine Films entered for the Exhibition of "Photography in Science and Industry".

Wednesday, November 11

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Prof. A. W. Ashby: "Agriculture To-day and To-morrow", 1: "Efficiency and Output in Agricultural Systems".

Thursday, November 12

INSTITUTE OF FUEL (at the Connaught Rooms, Great Queen Street London, W.C.2), at 2.30 p.m.—Dr. G. E. Foxwell: "The Provision of Smokeless Fuel for Post-War Reconstruction".

PHARMACEUTICAL SOCIETY (at Friends House, Euston Road, London N.W.1), at 2.30 p.m.—Prof. J. C. Drummond: "Nutrition".

Friday, November 13

ASSOCIATION OF SCIENTIFIC WORKERS (at the Royal Photographic Society, 16 Princes Gate, South Kensington, London, S.W.7), a 6.30 p.m.—Dr. H. Mandiwall: "Technical Cinematography in Colour"

Saturday, November 14

GEOLOGISTS' ASSOCIATION (at the Geological Society, Burlingto House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. C. E. N. Bromehead: "The Early History of Water Supply".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on o before the dates mentioned:

TEACHER OF GENERAL SCIENCE SUBJECTS, and a TEACHER O ENGINEERING SUBJECTS—The Principal, Luton Technical College Luton, Beds. (November 12).

SPEECH THERAPIST TO THE ISLE OF ELY COUNTY COUNCIL EDUCATION COMMITTEE—The School Medical Officer, County Hall, March Cambs. (November 12).

LECTURER IN CHEMISTRY AT THE HULL MUNICIPAL TECHNICA COLLEGE, CHIEFLY FOR INORGANIC CHEMISTRY—The Director c Education, Guildhall, Hull (November 16).

HEADMASTER OF THE GUILDFORD JUNIOR TECHNICAL SCHOOL—The Chief Education Officer, County Hall, Kingston-upon-Thame (November 17).

BIOCHEMIST FOR RESEARCH WORK OF NATIONAL IMPORTANCE I THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY—The Secretary National Institute for Research in Dairying, Shinfield, Reading.

LECTURER-IN-CHARGE OF CHEMISTRY—The Principal, Handswort Technical College, Golds Hill Road, Handsworth, Birmingham 21.

LECTURER ON WORKS ORGANIZATION AND MANAGEMENT—Th Principal, West Ham Municipal College, Romford Road, Stratfor London, E.15.

ASSISTANT MASTER TO TEACH SCIENCE AND MATHEMATICS IN TH JUNIOR TECHNICAL SCHOOL FOR THE BUILDING INDUSTRY—Th Director of Education, Education Office, South Parade, Nottingham

TWO INSTRUCTORS FOR DAY CLASSES FOR TRAINING OF MARIN ENGINEERS, at the Stow College, School of Engineering—The Directo of Education, 129 Bath Street, Glasgow, C.2 (November 20).

GRADUATE WITH GOOD HONOURS DEGREE, FOR STATISTICAL RESEARCH—The Secretary, Rothamsted Experimental Station, Ha penden, Herts.

SOCIAL SECURITY AND SOCIAL SERVICES

THE interdepartmental Committee on Social Insurance and Allied Services under Sir William Beveridge's chairmanship, set up to survey the existing schemes of social insurance and allied services, including workmen's compensation, and to make recommendations, the report of which is expected shortly, is dealing with a problem that closely concerns one of the great purposes of the nations now fighting for freedom and for a civilization based on respect for human personality. The idea of social security springs from the deep desire of men to free themselves from the fear of want. To realize this idea the causes of insecurity must be removed wherever possible, and the individual assured of that protection against the common risks of life which he cannot provide by his own unaided efforts.

The fact that the dangers and uncertainties of war stimulate many of the highest virtues of individual men and women should not lead us to underrate the great significance of freedom from want. When insecurity lasts for years and becomes part of a nation's life, its effects are just as deadening as those of unbroken security. For the last twenty-five years more than half the population of Great Britain has lived on the knife-edge between poverty and destitution, and the fear of falling into one or the other has stultified initiative and led to a desperate saving for the future at the expense of the present. Various stop-gap social services relieved, but did not cure, poverty and unemployment. We are at last coming to realize that the survival of democracy after the War depends on the replacement of unemployment by full employment and the reconciliation of security with freedom.

It is a significant sign of the times that recognition that the achievement of social security depends both on social and economic planning and on the willing acceptance by a free community of the sacrifices and restrictions involved is becoming more widespread. It is elaborated in a notable broadsheet, "Planning for Social Security", issued earlier in the year by Political and Economic Planning (P E P), which is based on a memorandum submitted to the Beveridge Committee. It is also implicit in one of the latest Studies and Reports of the International Labour Office, "Approaches to Social Security: An International Survey". This latter report does not merely round off the long series of studies of the International Labour Office on social insurance and assistance by reviewing the contributions to social security of these modes of bearing social risks. It is also intended to prepare the way for planning a complete social security programme in readiness for post-war reconstruction.

The resolution on aims and functions of social insurance, adopted at Havana in December 1939 by the Second Labour Conference of the American States which are members of the International Labour Organisation, shows the extent to which the social security ideal had taken shape in the minds of

American Governments before President Roosevelt's famous Four Freedoms speech or the Atlantic Charter. The resolution is appended to "Approaches to Social Security", the whole forming an admirable survey of the essentials by which the proposals of the Beveridge Committee will in due course be judged. The essay is a statement complementary to the P E P broadsheet, which is limited to a discussion of British practice and to British proposals, the merits of which are the more clearly seen against this background of general tendencies and experience.

A brief survey of social insurance shows clearly that responsibility for meeting social needs has been dispersed among numerous agencies, without much regard for plan or order, and the illustrations given in the third chapter of "Approaches to Social Security", on co-ordination of social assistance and insurance into a coherent system of social security, indicate the measure of what remains to be done to establish a system affording reasonable security for all who need it. Moreover, it must be recognized that security is a state of mind as well as an objective fact. To enjoy security there must be confidence that the benefits will be available when required, and to afford security, the protection must be adequate in quality and quantity.

Elimination of the causes of social insecurity consolidates and improves the structure of society, but social security policy can only be planned as part of a larger programme which includes measures for promoting employment and maintaining it at a high level, for improving nutrition and housing, multiplying facilities for medical care and widening opportunities for general and vocational education. Social security services are promoted by economic adjustments that make for the expansion of employment and for the distribution of income so as to procure the essentials of decent living, with due consideration for family charges. Such adjustments facilitate the financing of social security schemes, not only tending to keep benefit expenditure within bounds, but also to reduce it, since improved conditions of life and labour reduce the frequency and severity of social and industrial risks.

Compared with this survey, the P E P broadsheet is much more forthright and critical. Its major interest lies, however, in the constructive proposals advanced in regard to principles of reconstruction and a Ministry of Social Security. It puts forward a provisional scheme for a process of reconstruction which might extend over the next thirty years. It is an examination of basic principles and an attempt to define the objectives of long-term reconstruction, but it does not discuss secondary or immediate issues.

Besides the establishment of a national Plimsoll line of goods and services, the State must assume the wider duty of planning the use of our economic resources and man-power for full employment and maximum welfare. The building of post-war social security, moreover, will depend on acceptance by the citizen of stronger obligations and new compulsions. The opportunities and responsibilities which enhance the freedom of every citizen by making his rights real can only be enjoyed when the price is paid o accepting expert advice and skilled services to find work, to be trained or transferred for work, and to keep fit or to be speedily restored to health and independence. If we can get away from the futility o pressing a man to train for a job which does not exist; or of putting a sick man on to an inadequate allowance and driving him back prematurely into industrial conditions which can only undermine his health again, and remove some of the administrative absurdities and complexities, we shall have little cause to fear that the development of a social security system will sap the morale and independence even of the nation's least responsible elements.

The first essential, according to *Planning*, is therefore the establishment of a Ministry of Social Security to take over, among other things, administration o all income-maintenance services.

In regard to detailed services, the broadsheet suggests the unification of the medical services by divorcing them financially and administratively from National Health Insurance and from public assistance and organizing them in one national system which provides its services to all citizens as a right. To extend the scope of the National Health Insurance scheme to include persons of "like economic status" and the dependants of all insured persons, and to afford a far wider range of skilled services, as suggested by the National Conference of Friendly Societies, ar regarded as likely to impede rather than promote the unification of health and medical services into a comprehensive national system. It is a cumbersome approximate to the ultimate solution visualized by the Royal Commission of 1926 of "a carefully built up service organized on a single local basis in which all varieties of preventive and curative work find thei appropriate place".

The advantages of a system in which all medical services are provided on the basis of commo citizenship to every member of the community ar detailed, and the idea of the health centre and o co-operation and team-work among doctors and close contact with specialists, with the benefit to the genera level of medical work, are well set forth in the broadsheet. Similar points were stressed by the Dawso report of 1920 and developed in the recent report o the Medical Planning Commission of the British Medical Association, as well as in the report o National Health Services written by Dr. Jane Campbell for the British Association for Labour Legislation. While the local health centre may provide ne opportunities for active citizenship on a neighbourhood basis, a reconstructed income-maintenance system can clearly hold no place for administratio of incapacity cash benefits by approved societie That system must disappear, since the only approve society required is the nation itself.

Naturally enough, the broadsheet does not go int the detail of the recent report of the British Medical Association's Committee on Industrial Health i Factories, but it recognizes the contribution whic such a Board through its industrial medical servic might make towards extending first-aid services an raising their quality—a field in which air-raid pr cautions should not be without effect—as well as in passing on research problems to the Industrial Health Research Board. Any step which tends to stimulate industrial health research indeed merits careful examination, and among the further suggestions of *Planning* are, first, the development of an adequate system of first-class centres and departments for traumatic surgery, and, secondly, the creation of a proper system of special centres for diagnosis and treatment of occupational diseases and for research into their causes and conditioning factors. Here the British Medical Association's Committee on Industrial Health in Factories has rightly stressed the importance of co-operation between the medical profession, scientific workers, the factory inspectorate, employers, social workers, and the workers and their organizations. Finally, the Board should be responsible for vocational training schemes as well as entrusted with the care of all physically handicapped persons who might be rendered fit to engage in a remunerative occupation, and it should maintain a specialized service for placing disabled workers. The whole network of services involved in medical rehabilitation is so intimately bound up with other medical services, including hospitals, that they should be provided and controlled by the same authorities which are responsible for all the major medical services, although the Board should have powers of supervision and inspection of facilities.

This valuable broadsheet makes it unmistakably plain that any real unification and reconstruction of the social services in Great Britain will involve an immense amount of educational work to ensure the full co-operation, not merely of the numerous societies and local authorities concerned, but also of the individual citizens. It is the more welcome, therefore, that such a document should have appeared in advance of the Beveridge report, and that attention should also be directed to a scarcely less ambitious project in the Americas. The conference which met at Santiago de Chile affords evidence that in America also resources are being pooled in a positive effort to realize the common ideals of freedom from want and fear. A committee has already been constituted for the systematic and continuous exchange of information among the social security institutions of the American countries, and has set as its goal the establishment in each country of compulsory social insurance, covering industrial accidents and occupational disease, sickness, maternity, old age, invalidism, premature death, and involuntary unemployment, and applying to self-employed peasants and domestic servants as well as to industrial and commercial workers.

The case for a comprehensive and well-planned system in Great Britain could scarcely be better put than in the P E P broadsheet, and that such widespread attention should be given to this question of social security is a hopeful sign. It should not be forgotten that domestic policies, by promoting full employment and purchasing power, have a most favourable reaction on those difficult problems which will be encountered in the reconstruction of world trade after the War. Already the U.S. National Resources Development Board, in its report for 1942 now before Congress, demonstrates that planning for social security finds an accepted place in the post-war plans of the United States. While it is reasonable that the Government should decide to await the Beveridge report before taking any action in regard to social services, there will be grave disappointment if there is delay in implementing a real social security policy and programme based on the recommendations of that report. Failure to do so would be a blow both to the immediate war effort and at the post-war aims and association of the United Nations.

THE CASE FOR PASTEURIZATION

The Pasteurization of Milk

By Prof. G. S. Wilson. Pp. xii+212. (London: Edward Arnold and Co., 1942.) 18*s*. net.

THIS is a well-planned, well-written and well-documented book, but with a title that may, to some, give a slightly wrong impression of its contents. It concerns itself almost entirely with one main theme—a reasoned statement of the medical evidence in favour of the pasteurization, or effective heat treatment, of all milk. The bacteriological, particularly the public health aspects of pasteurization, as might be expected from Prof. Wilson, are treated with care and thoroughness, and a balanced summary is given of the relevant nutritional findings of the past ten or fifteen years. It is, however, no manual for the pasteurization engineer or technologist—that book has still to be written—and the economic, legislative and administrative aspects of milk processing also are only very briefly touched on.
